Authorized Translation.

Translator's Preface.

In the translation of Malkmus' "Grundriss der Klinischen Diagnostik" we have endeavored simply to reproduce the author's ideas with the hope that the English and American Veterinary Students may thus be provided with a text-book for which they have long felt a need. The needs of the students in the College of Veterinary Medicine of the Ohio State University have been the direct cause of the hurried undertaking of this work. A few short notes which we thought proper to add here and there, throughout the book, have been placed in [ ].

Columbus, O.,

David S. White,
Paul Fischer.
Preface.

The only safe foundation for the treatment of animal diseases is a correct diagnosis of the malady. In therapeutic as well as in forensic veterinary medicine everything depends on a correct recognition of the disease. This is the most difficult part of veterinary medicine, and methodical training alone will enable the student to develop into a practicing veterinarian who can do justice to this demand.

The following little work which offers a great variety of material in a most condensed form is intended as a guide for the diagnostician in recognizing and understanding the symptoms of disease. Although it represents the result not only of personal, but of veterinary experience in general, for the sake of clearness and general appearance the names of the numerous authors have been omitted. The results of bacteriological research which have an important bearing on diagnostics have been given due prominence. I have also deemed it appropriate to call attention, at the proper places, to those diseases or conditions which are considered as factors in annulling, or setting aside a sale. It was necessary to append a brief description of the most common diseases in order to give the student a general idea of the character of the maladies that affect the various functional apparatus, thus refreshing his memory and enabling him to institute comparisons between what he learns from his lectures and sees in the clinic.

The true to life representations of the horse and cow, which are copied from the "Handbuch der Anatomie der Thiere für Künstler," I owe to the kindness of Prof. Dr. Ellenberger and Prof. Dr. Baum of Dresden. I here most kindly thank these gentlemen for their unselilish obligingness.

The publishing house of Gebrüder Jänecke have disregarded both costs and trouble in order to supply good illustrations and to give the book a neat appearance; to them, too, my gratitude is due.

Hannover, November, 1898,
Malkmus.

The Diagnosis of Diseases.

The object of practical veterinary medicine is manifold, but in the main it consists in the restoration of the destroyed health of our domestic animals. For this purpose a knowledge of the affected organ and of the character of the disease is indispensable, because this knowledge offers the only safe basis for a rational treatment and a correct prognosis.

Thus the art of making a correct diagnosis is not only the foundation upon which practical veterinary medicine rests, but it is preeminently that which elevates medicine to the dignity of a science.

Diagnosis is the art of determining internal changes of the body by the aid of externally visible or otherwise appreciable changes in the animal's condition or some of its organs.

Since disease is a deviation from normal conditions and physiological processes, morbid changes cannot be recognized without a knowledge of normal conditions.

In the classroom the student has no opportunity to study the physical characteristics and the physiological functions of organs in living animals; he must learn this from personal observation and investigation in the clinic. In the clinic he must cultivate his senses and learn to hear, see, feel and smell in order to be able to judge correctly.

In the course of his practice different species of animals are presented to the veterinarian for clinical examination. This gives rise to certain difficulties which, in the main, are based
on differences in anatomical structure and physiological function of the organs of different animals. The methods of examination are about the same for all species. One who has thoroughly learned the fundamental principles underlying the methods for the proper examination of a horse will have little trouble in adapting them to other animals. However, important differences in this respect will receive due consideration.

A further considerable difficulty in diagnostics, for the veterinarian, is his inability to determine the subjective feeling of a patient. Still, this is of less importance than the layman usually supposes. On the other hand, to compensate for this we are in a position, in all cases, to make a complete objective examination of the patient in any direction. In this respect we have an advantage over the physician who is frequently denied this privilege and is besides liable to be misled by the imagination, whim, shame or vanity of the patient.

A diagnosis consists in the determination of
1) The symptoms of the disease.
2) The diseased organ.
3) The character of the disease—its name.

A Symptom* is any observable deviation from the normal state or condition. Anatomy and physiology treat of the normal conditions and functions; Symptomatology treats of morbid conditions and of perverted functions.

The particular object of a clinical examination is the determination of symptoms; it must therefore include the external appearance and general behavior of the animal as well as a careful inspection of every accessible organ. To avoid mistakes or overlooking important factors we must conduct this examination according to a definite plan.

The best plan to follow is to take up the different functional apparatus in their physiological order and complete the examination of each in its turn. The beginner should memorize the scheme and follow it faithfully. This is no difficult task

*[Syn.—mark—note—sign—token—indication.]
since the arrangement is a physiological and therefore natural one.

We propose the following order of procedure:

I. *Anamnesis* (ascertaining previous history of case).
II. *Ascertaining the Status Praecens.*

A. **General examination.**
   1) Signalment of the patient.
   2) Habitus.
   3) Skin.
   4) Conjunctiva.
   5) Temperature.

B. **Special examinations.**
   6) Circulatory apparatus.
   7) Respiratory apparatus.
   8) Digestive apparatus.
   9) Urinary apparatus.
  10) Sexual apparatus.
  11) Central nervous system.

C. **Specific examinations.**
   12) Locomotion, exercise in harness or under saddle, etc.
   13) Diagnostic inoculations.
   14) Examination of lymphatic glands.
   15) Examination of the blood.

The anamnesis should be procured and the general and special examination should be made at least once during the first visit to the patient. If the diseased organ or organs have been ascertained they must be carefully re-examined at every subsequent visit, at the same time we must be on the alert for the appearance of possible symptoms in other organs.

The specific examinations are made only when necessary for clinching the diagnosis.

Sometimes external influences bring about certain conditions of the healthy body which must not be interpreted as symptoms of disease, although they might, under other circumstances, be such; e. g. a horse refuses its feed—this is a frequent occurrence in gastro-intestinal affections or in the
course of severe general diseases, but it may also be due to an excitable temperament of the animal or to the fact that the food in itself is undesirable—spoiled, mouldy. Hence the practitioner must always endeavor to ascertain the cause of the symptoms, whether the deviations from the normal are really due to disease or to external conditions.

Rapid respiratory movements may be due to a disease of the respiratory apparatus or to some other affection; again, they invariably occur after bodily exertions, and high temperatures, even when the animal is at perfect rest, will cause the respiratory movements to become accelerated.

To avoid confusing symptoms produced by muscular exercise, or other efforts on the part of the animal, with symptoms of disease, the patient should first be examined in a state of rest. Furthermore, all conditions that could possibly influence normal physiological processes must ever be taken into consideration; for example, we will mention age, oestral period, pregnancy, fright on part of the animal, etc.

After noting the symptoms of the disease we come to the most difficult part of clinical diagnostics, viz:

**Ascertaining the Diseased Organ.** There are only a few symptoms which point with certainty to an affection of a definite organ, fewer still enable us to recognize the character of the disease; these latter are called *pathognomonic symptoms*. As a rule all symptoms must be first noted and then considered as a whole, always bearing in mind the principles of general and special pathology.

We distinguish different kinds of symptoms:

1) *Direct symptoms* are due to the fundamental disease or morbid process.

2) *Indirect or accidental symptoms* are due to complications of the fundamental disease.

3) *Local symptoms* belong to the affected organ or to the disease center.

4) *General symptoms* belong to the body as a whole
and are due to a sympathetic relationship of all the organs.

To determine the affected organ all ascertained symptoms are carefully reconsidered in the order in which they were determined. The healthy apparatus are for the time being disregarded, the diseased apparatus are given special consideration.

A variation in the normal functional activity of an organ does not in itself indicate disease, it may simply be a compensatory variation (one due to an opposite variation in a similar organ) due to the primary morbid condition. The therapeutist's object is to ascertain the primarily affected organ, bring about a cure in this and secondarily cause the sympathetically affected organ to regain its natural condition and activity.

To discover the primarily affected organ requires a knowledge of the morbid processes that take place in each organ and of the direct, indirect, local and general symptoms produced by them. This requirement is still more important for the final aim or ultimate purpose of diagnostics, viz:

The recognition of the disease itself according to kind, etiology, intensity and duration. The method of examination of each organ will therefore be followed by a short description of the most important diseases of each. A correct diagnosis and a rational treatment requires a thorough investigation into the cause of the disease.

It is not enough to diagnose a nodular, itching and spreading eruption of the skin, we must also determine the cause or our prognosis and treatment cannot be correct and rational. Such eruptions are due to various causes and an exact knowledge of them is an important item. The same may be said of affections of internal organs.

A final diagnosis is made either by considering the determined symptoms directly (direct diagnosis) or by a process of exclusion, i.e., we review in our mind all diseases in which the symptoms ascertained occur, or in which some of these
symptoms occur, and then we exclude those diseases in the course of which, if present, we usually observe additional symptoms (differential diagnosis).

Following one or the other of these methods usually suffices to make a diagnosis. Not infrequently, however, even the experienced practitioner must content himself with limiting his diagnosis to a statement of the general character of the disease and reserve the privilege of expressing his final opinion (special diagnosis) pending further observation and developments. This is particularly the case in the first outbreaks of infectious diseases when localized changes are absent. We also distinguish between a definite, a probable, and a possible diagnosis.

The difficulties encountered in diagnosing internal diseases, vary considerably; in some cases a good anamnesis suffices as a basis for making a definite diagnosis: epilepsy, parturient paresis. In other cases the experienced practitioner requires but a glance at the patient: tetanus. The rule, however, is never to make a diagnosis until a thorough and careful examination of the patient has been made; but here, too, carefully cultivated powers of observation and extensive experience go a good way. To acquire either of these of course requires continued carefully and methodically conducted examinations.

If the diagnosis cannot be made definite in every respect, be cautious in your prognosis and therapeutics.
I. Anamnesis.

Full statements on the part of the owner or attendant, procured by cautious questioning, concerning the previous condition of the patient, the beginning and previous course of the disease (anamnesis) are of great importance in diagnostics, in fact there are some diseases, like epilepsy, for example, that can as a rule be diagnosed in no other way because it is only in exceptional cases that we have an opportunity to observe a typical epileptic fit.

As far as the veterinarian is concerned the anamnesis is limited to the observation of the immediate surroundings of the animal. In questioning attendants speak to them in a pleasant tone and manner and use words and expressions with which they are familiar; this tends to infuse confidence and the result is that the information thus obtained will be more apt to be reliable.

A well drawn up anamnesis speaks for the technical ability of the veterinarian as well as for his knowledge of the etiology of the diseases of our domestic animals which are kept under the most variable conditions.

1) How long has the animal been sick? We may learn by this question whether the disease is an acute or a chronic one, and perhaps also the stage of development which the disease has reached. Frequently the time given by the owner or attendant is much shorter than the actual duration of the disease.

2) What symptoms has the animal shown? In the beginning? Later on? The objective observation of the owner must be carefully sifted out from his subjective interpretation of them.

3) What, in your opinion, could be the cause of the disease? We cannot search for the causes until we know the symptoms.

\textsuperscript{1} ανάμνησις, a recalling to mind; recollection.
Where and under what conditions did the animal get sick? Feed, care, etc., play an important role in the etiology of diseases of animals; therefore the veterinarian must be informed not only as to the kind and character of the feed but also as to soil conditions, water, etc., otherwise he cannot intelligently trace the cause of the disease.

4) A number of animals affected by the same disease always points to a common cause, viz.: infection or intoxication (poisoning). The frequent recurrence of a disease in the same stable points to the existence of a permanent cause.

5) It is of especial importance for the veterinarian to know whether any previous treatment has been resorted to and what effect this may have had. Quacks often administer draughts containing solid particles in suspension; these draughts, instead of taking their usual course may enter the trachea and thus produce a fatal pneumonia. In removing the contents of the rectum its wall or mucous membrane is also often injured. In such cases the veterinarian must exercise care and judgment and call the owner's attention to any existing danger.

Although the main points in the anamnesis should be determined before we begin our objective examination, other questions will present themselves in the course of the latter. Thus, when examining the larynx we may inquire whether the animal coughs, and when examining the digestive apparatus inquire as to condition of bowels, frequency of evacuation, etc., in this way gradually completing our examination.

The value of a good anamnesis consists in the fact that not infrequently it is sufficient to base upon it a definite diagnosis, i. e., careful objective observations of the layman may in some instances be substituted for our examination. However, the veterinarian must always be cautious in complying with the oft made request of owners to treat their animals in absentia. Although the medicines prescribed under such conditions may do no particular harm, rational treatment thus delayed may prove to be a positive injury.
II. Ascertaining the Status Praesens.

To determine pathological phenomena we resort to all those methods which throw light upon the physical state and functions of the different organs. In doing this we should endeavor to follow a definite plan and not proceed without system. The following methods are generally employed and in the order given:

1. Inspection.

In examining the different parts of the body it is always best that we first regard that which can be observed with the unaided eye. Students are apt to lay their hands upon the patient too soon. Superficial abnormalities are described according to their seat, size, color and other external manifestations; the size and form usually being compared with common objects, unless an exact description is desired when actual measurements are made.

The odor emitted by the se- and excretions and the respirations is also noted.

In designating the seat of visible pathological conditions the exact anatomical region occupied by them should be indicated.

Regions of the Body,

1. Head.

A. Face.

1. Nasal region with dorsum of nose, tip of nose, nasal openings. [Nostrils.]
2. Labial region, with upper and lower lips, interlabial space and chin.
4. Infraorbital region.
5. Ocular region.
6. Masseteric region with maxillary articulation.
7. Intermaxillary space.

Fig. 1.

B. Forehead.
8. Frontal region.
9. Occipital region with forelock.
10. Temporal region with the temporal fossa, infra-temporal groove and auricular region. [Ears.]

II. Neck.
11. Parotid region, which merges below into the laryngeal region.
12. Tracheal region with jugular groove, at the lower end of which is the supra-clavical fossa.
13. Cervical region with crest and mane.
III. Chest.
15. Withers and dorsal region.
16. Lateral pectoral region [sides of chest] with scapular region, cardiac region, costal region.
17. Sternal region.
18. Anterior pectoral region. [Breast.]

IV. Abdomen.
19. Epigastric region with xiphoid space.
20. Mesogastric region with umbilical space, iliac region (flank with ‘hollow of flank’) and the lumbar region.
21. Hypogastric region with pubic and inguinal region.

V. Pelvis.
The different divisions of the pelvis are named according to their anatomical parts; the sacral region is called the croup, the external angle of the ilium the ‘hip,’ just below the anus the perineal region; the anal region, pubic region and inguinal region.
The various portions of the extremities are designated according to the names of the bones constituting them.

2. Palpation.

Palpation consists in feeling the part to be examined with the hand or finger tips. Its object is to gain information through the sense of touch as to the consistency, extent, temperature and sensitiveness of morbid processes, and permit us to recognize abnormalities which do not lie far below the surface. Palpation is of especial importance in taking the pulse. The abdominal viscera can be explored (palpated) through the rectum and the anatomical position, and condition of the contents determined.

From the difference in consistency of the parts palpated, conclusions as to their physical nature may be drawn. The following peculiarities may be distinguished on palpation:

1. A part is doughy when it feels soft and accepts finger imprints which it retains for a few moments, when the depressions are again filled. Tissue is of a doughy consistency when infiltrated with serum: (edema).

2. A part is firm when it is of the consistency of normal liver. According to the part’s resistance to the touch it may be
firm, tendinous, solid or hard as bone. A cellular infiltration of tissues (phlegmona) or the presence of tumors made up of cells, will lend to a part a firm consistency.

3. A part is fluctuating when it is soft, elastic and undulates on pressure. Only fluids admit of such a rapid transmission of pressure (pus, blood, lymph, serum). If the tissue surrounding the fluid is not tense, waves are seen to pass over the surface of the swelling (true or soft fluctuations). Soft-elastic (fat) tissue or tissue impregnated with a quantity of fluid may also show fluctuation; this undulating consistency is spoken of as pseudo-fluctuation.

4. A part is emphysematous when it presents a puffy swelling which crackles and shifts on palpation; it is due to the presence of air or gas in the tissue (emphysema).

3. Percussion.

By percussion we understand striking the surface of the animal body so that the parts thus set in vibration emit audible sounds. The "percussion-sound" thus produced will differ with the physical condition of the vibrating parts, and these differences are so well marked that definite conclusions can be drawn from them.

Methods of percussion. Percussion can be practiced without the use of instruments [so-called immediate percussion] on small animals or large animals thin in flesh. The index or middle finger of the left hand is held firmly against the part to be percussed and struck with the middle finger of the right hand. The striking finger should be held somewhat curved and stiff. The advantage of immediate percussion lies in the facility with which the finger may be placed between the ribs and amid the long hair of some dogs and the wool of sheep. For the larger animals the sounds obtained from this finger-to-finger method of percussion are not definite enough for practical use.

In the immediate method of percussion, however, the
sound can be augmented by employing the percussion hammer to strike the finger which is applied to the part (finger-hammer percussion).

The pleximeter and hammer (plexor) are most commonly used in practice [so called mediate percussion] as they permit not only of gentle percussion but the part to be examined can be struck a heavy blow which sets deep-lying parts into vibration. The pleximeter should be so held that its whole surface is in firm contact with the part to be percussed. In thin animals the pleximeter should never be applied across two ribs, but should be made to occupy an intercostal space that the air between it and the body does not modify the sound. The force with which we use the hammer depends upon the thickness of the walls of the part percussed. [In fat animals it is necessary to use more force than in lean ones].

Usually two or three strokes suffice to bring out clearly the character of the sound. For comparison it is advisable to percuss corresponding parts on each side of the body.

For a better perception of the percussion-sound it is advisable to select a suitable place. A room with closed doors is the best; in very large rooms or out of doors the application of percussion is never satisfactory.

As a rule large animals are percussed while standing, though small ones may be placed in a recumbent position upon
a table. Although gentle animals may stand quietly during the operation, very nervous horses or stubborn cows sometimes resist. They can generally be quieted by speaking to them in an assuring tone and by omitting all rough usage of the instruments. Dogs and cats may be held by their owners or an attendant.

**The Qualities of Percussion-Sounds.**

A body can only then produce a sound when it has lost its equilibrium and vibrates by virtue of its elasticity. Two principles from the basis of percussion:

1. Solid, airless parts of the body give forth a flat sound of short duration and little intensity. Such a sound is called *dull*, femoral or empty.

2. If an air-containing organ is set in vibration it produces a sound of considerable intensity, duration and tone, the so called *resonant* sound.

![Fig. 4.](image)

![Fig. 5.](image)

![Fig. 6.](image)

- a. The stronger the percussion the larger is the part which vibrates and the fuller the sound.
- b. The thinner the overlying tissue of the thoracic wall the more lung tissue will vibrate and the fuller the sound.
- c. If the volume of the air containing organ is small in itself then the sound is correspondingly less intensive.

The clearness of the sound depends upon the volume of the air-containing organ which is vibrating.
This explains the varying intensity of the sound over different portions of the chest wall when the percussion blows are applied with equal force. The resonant sound gradually merges into the dull femoral as we approach the forward and upper portions.

The resonant sound may be subdivided into:

1. The *tympanitic* sound, which approaches a musical tone.
2. The *full* sound (pulmonary resonance).

The tympanitic and full sounds are both resonant in character, and in both the degree of clearness can vary until they become identified with the dull sound. The intermediate stages are comparatively dulled and dull *tympanitic*.

**Occurrence of the Different Qualities of Percussion-Sounds.**

According to the above classification there are three kinds of percussion-sounds: The full (pulmonary resonant), the tympanitic, and the empty.

1. The full sound is found over normal lung, the air in the alveoli, and the lung tissue, and thoracic walls vibrating. When the intestines are so distended with gas that when percussed their walls vibrate with their contents, a full sound is emitted.

2. The tympanitic percussion-sound has a varied origin. It is heard:

   a. Over cavities containing air which communicate with the outside world, their walls being either firm or yielding: trachea, caverns in the lung communicating with bronchi. The pitch of the sound depends upon the size of the cavern and its communicating opening.

   b. Over enclosed air-containing cavities the walls of which are little distended, hence over the stomach and bowels.

   c. Over lung tissue the tension of which has become diminished. (atelectasis, beginning hepatization).

3. The empty (femoral) sound is heard when percussing over solid tissues which do not contain air. As the most
forcible percussion does not produce vibrations at a point more
than 10 cm below the surface, a dullness can be perceived over
the normal lung when the chest walls are covered with heavy
muscles, fat, or edematous swellings.

The sound is comparatively dulled when air-containing
parts of limited dimensions are percussed (borders of the lung,
and under thick thoracic wall) or if small airless spaces lie
amid those containing air (nodular thickenings in the lung).

During the application of percussion we should note the
resistance the part offers to the hammer or striking finger.
[To understand what is meant by this the student should
strike with the plexor some solid object, as a brick wall, and
compare it with the feeling experienced when the human chest
is percussed]. By placing the index finger on the back of the
hammer the resistance can be better appreciated. From the
resistance the amount of vibration that can be induced in the
underlying parts may be determined, the greater the former
the less developed the latter. For this reason solid, airless
parts like muscle give a shallow percussion-sound and causes
the hammer to suffer a jar when they are struck.

**Determining the Boundaries of an Organ from the
Percussion-Sound.**

The boundary of an organ can be determined by percus-
sion only when the organ lies superficially and emits a percus-
sion-sound which differs from that of its neighborhood. For
this reason the boundary of the heart against the lung or the
lung against the bowels may be defined by percussion.

4. **Auscultation.**

By Auscultation, applying the ear to a part, we seek to
obtain information, through the sense of hearing, as to the
physical state or condition of deep-lying organs. For this
reason auscultation is practiced upon the heart, lungs and in-
testinal tract.
In human medicine auscultation is usually practiced with the help of instruments (mediate auscultation), the so called stethoscope etc. being employed. [In veterinary medicine, however, the use of such instruments is very limited, the heavy hair coat materially interfering with and so modifying the sounds that false conclusions may be drawn. To a limited extent the phonetoscope is useful in auscultating heart sounds, but the hairs over the cardiac region should first be thoroughly moistened or oiled].

By simply applying the ear firmly to the part, better results can be obtained than by the use of instruments. In case the skin is dirty, blistered, or the animal is lousy, a towel can be placed between it and the ear. To guard against being bitten or kicked an attendant should hold the patient by the head. In large stables containing a good many animals the noises they produce may interfere with auscultation; if it is essential to diagnosis or prognosis, the patient should be examined in some quieter place.
A. The General Part of the Examination.

1. Signalment.

By the Signalment is meant a description of the patient for identification by peculiar marks or characteristics. For forensic purposes and special cases the proper taking of the signalment is of great importance. It is further of some value in a diagnostic sense and is sometimes taken into consideration therapeutically.

It includes:

I. Kind of animal. Many diseases are peculiar to certain genera while they do not occur in others. This is especially true of the infectious diseases as, for instance, the horse suffers from strangles, and glanders; the ox from contagious pleuropneumonia (lung plague), malignant head catarrh, and swine from hog cholera and swine plague. There are also special sporadic diseases which owe their origin to the peculiar anatomical or physical makeup of a genus. As examples, may be mentioned traumatic pericarditis of the ox; ruptures of the stomach and roaring in the horse.

II. Sex. Diseases of the sexual organs are not common in animals, but sex is of influence in the appearance of some diseases. In stallions inguinal hernias which cause symptoms simulating colic occur; mares during the period of heat may act as if they were suffering from some brain disease (act like dummies) or may balk or show obstinacy when at work. In
the ox urethral calculi are not uncommon. The condition of pregnancy is as of great importance from the diagnostic as from the therapeutical standpoint, because this condition may induce physiological symptoms that would be considered pathological in non-pregnant animals. In pregnant animals caution is demanded in the choice of drugs.

III. **Color and white markings.** For diagnosis the color and markings are of less importance. White horses frequently suffer from melanotic tumors that are either superficial or located in internal organs. White areas are more predisposed to exanthemas, sunburn and scratches.

IV. **Age.** Many diseases occur either exclusively or generally in youth. Rhachitis, diseases of the navel, strangles in colts, scour in calves and distemper in puppies are examples. In old individuals diseases due to the animal’s use are more frequent as are also chronic diseases of organs.

The age is also of influence upon the prognosis in as much as healing, all things else being equal, is more to be hoped for in the young individual than in the old one. In old animals where the prognosis is a doubtful one all treatment is frequently omitted on economic grounds.

V. **Size.** Size is of importance in posology only.

VI. **Breed.** In well bred animals the reaction against the encroachment of disease is more energetic and the symptoms are more pronounced. Certain breeds are more able to withstand infectious and sporadic diseases than others, this must be considered in making a prognosis. Breed is also taken into consideration in the treatment of diseases. Well bred, fine skinned, sensitive horses yield to the action of certain drugs more readily than those of the opposite type. This is especially true where outward applications (turpentine blisters) are to be made.

VII. **Use and Care.** The use to which the animal is put and the care taken of it is closely connected with the etiology of disease. Certain uses and also neglect, predispose to varied forms of disease.
2. Habitus.

By the term *habitus* we mean the general or external aspect or characteristic appearance of the patient, which is determined by its physical attitude, condition, conformation and temperament. It offers a convenient aid in diagnosis, one that can be readily observed and that, in many respects, is of great importance. Not infrequently a diagnostic conclusion in a clinical case is reached largely through the impression the patient makes upon us by its *habitus*.

1. Attitude of the patient. Healthy horses as a rule remain standing during the day, or if lying down they immediately rise to their feet at the approach of a stranger. They will frequently lie flat on their side with feet extended, provided the halter strap be long enough and the stall of sufficient width.

Healthy cattle (bovines) lie down often during the day, especially just after feeding, and they are not so prone to rise when approached. They seldom lie flat on the side, but in *sternal decubitus* the limbs are folded under them.

Healthy sheep jump up when approached and usually run away.

The attitude of sick animals whether standing or lying down is often of value in diagnosis.

Standing attitudes assumed during disease. The head is held stiffly and extended in pharyngitis, [tetanus], cerebrospinal meningitis, muscular rheumatism, malignant head catarrh of the ox, and in acute encephalitis of sheep and goats.

Very sick animals usually hold the head down, and assume a relaxed, languid attitude, the ears drooping; horses rest their feet alternately.

Cows suffering from severe vaginitis stand with arched back, tail held high, and legs spread apart. They do not "stand over" readily in the stable, and if driven stop repeatedly to urinate.

A stiff, quiet attitude, avoiding moving as much as possi-
ble, is characteristic of very painful affections in the chest or abdominal walls (pleurodynia, Pleuritis. Peritonitis). Stallions suffering from incarcerated inguinal hernia and oxen with peritoneal hernia (guttie) stand with the hind leg of the affected side held backward and outward.

**Unphysiological attitudes.** Animals afflicted with brain troubles (acute or sub-acute encephalitis, "dummies") very often assume unnatural attitudes. Horses stand obliquely in the stall, the head in a corner, resting against the wall or sunk under the feed box. The limbs are drawn well up under the abdomen, and not infrequently one leg is placed in a very unphysiological position, perhaps crossing its fellow of the opposite side. "Dummies" stand unusually quiet and seem oblivious of their surroundings. They move without energy, and are backed with the utmost difficulty. (See under "Central Nervous System," "Examination of Dummies").

*Continued standing* is observed in:

a. Old, worn-out horses.

b. Pneumonia and Pleuritis. As a rule if the animals lie down in these diseases it is on the diseased side, and for the following reasons: because the slight pressure of the ground against the body ameliorates the pain, and the pleuritic exudate (the effusion in the chest) does not encroach so much upon the heart and the still healthy lung. The respirations are always more difficult when the animal is lying down. [In peritonitis resulting from castration horses very commonly remain standing; when forced to move they do so with hind legs held in abduction, advancing very stiffly].

c. Severe Dyspnoea. The head is held extended to allow the air the easiest possible access to the lungs, thus facilitating inspiration.

d. Horses suffering from acute diseases of the brain.

e. Horses suffering from Tetanus. They stand with legs braced *like a saw horse*, the head somewhat extended and held high. It is very difficult for them to step sideways. The facial expression is anxious, the *membrana nictitans* appearing
plainly before the eye; the tail is carried high and stiff, and the gait inflexible and laborious.

Restless Standing: Most commonly seen in horses suffering from colic. They are restless, lie down, roll, and get right up again. In many cases it is only with difficulty that they can be kept on their feet; when down it may be equally hard to drive them up. They look often at the flanks, paw, strike the belly with the hind feet, switch the tail, and stretch as if to urinate without voiding urine. At times they sit up like a dog. Like symptoms but of shorter duration are observed in the ox suffering from invagination of the intestines, torsion of the uterus in cows and from urethral stones and peritoneal hernia in steers.

Lying postures assumed during Disease. Animals found lying down and that can not be made to rise should be examined very carefully. We should first try to drive them up by speaking to them in a sharp tone of voice and assisting them by mechanical means. It is important to determine whether they are really unable to rise or whether they are obstinate and will not rise (maligners).

If the animals have lain for a long time on one side, it is advisable to turn them over before attempting to drive them up. The same should be done when after a fruitless effort to get an animal onto its feet, it falls back again to the ground and we make a second attempt to make it stand.

To bring recumbent horses to their feet it is expedient, after placing them on the sternum, to pass the end of a long halter rope through a convenient ring in the wall, and keep it pulled taught; the hind legs should be doubled under the body in a natural position and the fore ones extended in front. By speaking to the animal, striking it over the ears and nose, and lifting by the tail, we may assist it to regain its feet. When this method fails a sling should be placed under the body and the animal raised with block and tackle.

The ox is often hard to induce to stand up after it has been down for a time. It may be able to get up, but through obstinacy will not do so. Whipping and beating in such cases is usually of no avail; yelling in the animal’s ear, setting a dog on it or tying its nose shut may be tried. [By placing a rope around the body so that it passes beneath the brisket
in front and the ischii behind, we have improvised a handle by which several persons can lift the malingerer to its feet.

Animals are unable to stand:

a. In Tetanus. Horses suffering from tetanus, if down, are as a rule unable to stand up without help, as the spasmodic contractions of the extensors of the limbs prevent it. When recumbent, the upper pair of legs do not come in contact with the ground. The animals are very restless and bedewed with sweat.

b. In Azoturia. Horses suffering from acute azoturia make vain efforts to stand. They are sometimes only partially successful, the fore part of the body being raised and
supported by the front legs, but the hind limbs are unable to bear their share of the weight, breaking down under it.

c. In Spinal paralysis from Fractures of Vertebrae. The patients lose control of the hind parts which are no longer sensible to pain [pin pricks]. Sometimes, however, reflex spinal convulsions attend "broken back." Dogs with paralyzed hind parts usually sit sideways, the legs directed away from the body.

d. Anti-and-Post-partum Paresis. Occurs in cows before or after calving. The animals seem to be in comparatively good health, have a good appetite, but can not regain their feet. There are no further symptoms of disease or injury. They often lie stretched out on the side. [Prognosis is favorable].

![Cow with Parturient Paresis](image)

e. Milk Fever (parturient paresis). The cow lies in a comatose condition on the left side as if in profound sleep, the head resting against the right chest. Sensitiveness of the whole body is diminished.

f. Cramp of the Neck (cerebro-spinal meningitis). After showing symptoms of stiff, wry neck, while standing, paralysis follows. The patients lie flat on the side with the head drawn backward, the body convulsed with spasms.

Old, worn out horses are hard to get upon their feet once they have lain or fallen down. When animals are suffering
from severe pain in the legs and feet (founder) or when lying on an injured limb (fracture), they can as a rule rise only with the greatest difficulty. Colic patients, when down, generally do not get up promptly.

II. Condition. The condition of the animal is recognized principally by the rotundity and fullness of development of the body. Cold blooded horses usually have well rounded forms because the muscles are of large size and surrounded by well developed fat deposits. The condition as to flesh is influenced by the quantity and quality of the food and the use and purpose for which the animal is intended and fed. Continued hard work reduces the fullness of the body outline, causing the conformation to appear angular.

When the digestive tract is affected with disease, whether local or general, the condition of the animal becomes reduced. A gradual but continual loss of condition, notwithstanding that the appetite and food are good, always points to chronic disease, but not necessarily to disease of the digestive tract. When the digestive tract becomes diseased the appetite is impaired.

Depending upon the use and purpose of the animal we distinguish the following kinds of condition: Prime, very good, tolerably good, fair and bad. A gradual, progressive general emaciation is called Cachexia. Rapid emaciation appears in purpura hemorrhagica and in severe infectious diseases. Excessive corpulence (obesity) is common in bulls and dogs; in slaughterable animals it is desired.

III. Conformation. It is advisable to classify horses according to their use into heavy and light draft, carriage and saddle horses. The classification is based upon the animal's conformation. To judge of the conformation correctly we should take into consideration the depth of the body, breadth and depth of chest, curvature of the ribs, strength and angulation of the joints, and the attitude of the limbs when standing naturally.

Horses with flat, small chests possess poor staying qualities, the lungs corelatively being small. Horses with flat, not
well sprung ribs, tucked up abdomens and long limbs, are as a rule poor feeders. As such animals show continually poor appetites for food, the bowels are not kept well filled, hence the body appears deficient in depth. [The horseman speaks of such a conformation as being "herring gutted"]. Hearty horses which are good feeders, show on the other hand, better developed abdomens, the bowels being distended by the large quantities of food they contain. The more voluminous the food, the greater the circumference of the belly. [The abdominal circumference is further increased in pregnancy and in diseases causing exudates to accumulate in the abdominal cavity ascites].

**Constitutional Diseases of the Bones.**

*Rachitis and osteomalacia.* Both of these diseases are characterized by the bones being deficient in lime salts. Such bones possess little power of sustaining weight; hence they suffer change in form when the weight of the body must be borne by them.

a. *Rachitis* appears only in young animals, mostly in pigs and puppies. Pathologically the disease may be considered to be a remaining softness of the bones, the epiphyses becoming enlarged, the diaphyses bent An upward curvature of the spine is called kyphosis, a downward lordosis, a lateral scoliosis. Animals suffering from rachitis remain lying a great deal, find trouble in regaining their feet, and locomotion is difficult.

b. *Osteomalacia.* Fragility of the bones is seen only in adult animals (cattle). The animals lie down continually, are weak, eat but little, and becomes thin in flesh. The bones of the extremities become brittle; spontaneous fractures, decubitus, and death ensue.

**IV. Temperament.** By temperament we mean the mental attitude the animal assumes toward impressions perceived through the medium of the organs of sense. An animal's knowledge of what is going on about it is obtained through the instrumentality of the bodily senses of sight, hearing,
smell, and touch. We distinguish between a lively and a phlegmatic temperament, comparing the power of quick perception with its opposite slow comprehension. Too much tendency in either direction will affect the usefulness of an animal.

Animals of fiery disposition often show temper by being stubborn, vicious, balky, or they are very nervous, anxious, easily frightened, which reduces their economic value. Young animals, especially horses, are often restless and like to play.

Animals of a very phlegmatic temperament may be so slow to move as to impair their usefulness.

The sort of temperament possessed by an animal is shown by its external appearance. The countenance, expression of the eye, play of the ears, and quickness of movement form sources from which the temperament and disposition may be judged. The facial expression and eye give information as to the mental condition.

Blind horses are often scary; they employ the sense of hearing, moving the ears in a lively manner to take the place of the lost sense of sight, at the same time holding the head still. This may cause us at first sight to suspect that the animal is suffering from a brain disease. Old horses are not so sensitive to outside impressions as colts. Some colts, however, are little observing of their surroundings, appearing dull, stupid and lazy, without suffering from disease. Great fatigue produces temporary physical and mental depression also temporary loss of appetite in phlegmatic individuals.

Feverish diseases affect the temperament, making the animal affected sluggish in its movements. In animals of fiery temperament this is not so noticeable.

In animals suffering from severe, serious diseases, the temperament can become so changed that vices, such as cribbing, biting, kicking, etc., are no longer indulged in. The countenance appears blank, expressionless, staring, locomotion slow and unsteady. A few hours before the fatal termination of a disease, the normal tonus of the tissues is lost, the muscles relax, especially those of the face, forming the so-called Hip-
pocratic countenance (facies Hippocratica), one of the symptoms of approaching death.

3. The Skin.

The condition of the skin indicates the state of health. The condition of the skin is affected not only in local diseases of that organ, but in many maladies of a general nature, involving internal viscera. An examination of the integument, therefore, is of importance to diagnosis. The skin is examined by inspection and palpation; in local diseases the microscope is employed. An examination of the skin includes the following:

1. Condition of the hair coat. In horses in good condition the hair is usually short, fine, glossy, and lies smoothly. Horses running on pasture or kept in unsanitary stables, show a long, lusterless, rough, bristling, hair coat. If the condition of the hair coat is bad, notwithstanding good care and shelter, it may be assumed that the animal is suffering from ill health. The appearance of the hair coat is influenced mostly by chronic diseases. Temporarily the hairs may become erect when the animal is carrying increased temperature (chill) or from the effects of cold air or water.

Shedding of the hair. In horses and cattle a partial shedding of the hair occurs normally each fall and spring. In the fall the long, soft winter coat appears; this is shed the following spring. [Animals kept blanketed in warm stables retain a short hair coat throughout the winter.] Good care and proper food hasten the shedding of the hair, contrary conditions tend to postpone it. When the winter coat is retained during the summer months, it indicates chronic disease of nutrition.

When horses which have been poorly kept pass into good hands and receive nourishing food and good attention, an unusually early shedding of the winter coat follows.

Alopecia. A loss of hair over the whole or a large part of
the body (alopecia) sometimes quickly follows the recovery of an animal from a severe infectious disease (contagious pleuropneumonia of the horse). A gradual loss of coat accompanies chronic, cachectic diseases in sheep and dogs. In chronic diseases affecting nutrition the hairs become loose, and may be easily removed by pulling or rubbing. Horses clipped late in the season (November, December) grow short winter coats; when these are shed the following spring, the skin is left partially denuded of hair, giving the animal a half-naked appearance.

Where the hairs fall out in patches, and lesions are found in the skin, a disease of the integument is present.

II. The skin’s moisture. The skin is kept continually moist by the secretions of the sweat glands. In healthy animals at rest the supply of secretion is just sufficient to keep pace with the loss by evaporation, so that the skin does not feel wet but soft and pliable. The skin’s moisture is increased by exercise, high atmospheric temperatures and nervous excitement. Sweating does not become visible in swine, sheep, dogs, and cats.

In disease a more or less profuse outbreak of sweat (hyperidrosis) appears:—

1. when an animal is much weakened from acute or chronic disease.

2. in severe dyspnœa, where it is compensatory, assisting the lungs to throw off effete matter; stenosis of the anterior respiratory passages, diffuse pneumonias, pulmonary emphysemas, and organic heart diseases.

3. in painful maladies: founder, colic, enteritis.

4. in diseases painfully affecting the muscles: tetanus, epilepsy, azoturia, cerebro-spinal meningitis.

Normally, perspiration is accompanied by a hyperemia of the skin. If this congestion be absent, the sweat being excreted upon a cold skin surface “cold sweat” is spoken of, a process to be judged unfavorably from a prognostic standpoint.

Local sweating (hyperidrosis localis), or sweat appear-
ing on only one side of the body (hemidrosis) is seen at times to accompany diseases of the nervous system.

A decrease in sweat secretion (hypidrosis) can be so well developed that the skin feels dry (anidrosis). This condition can best be appreciated on the muzzle of the ox, the snout of the hog, or the nose-tip of the dog. These parts in healthy animals are moist and nearly cold. During high fever, severe diarrhea, diabetes insipidus (polyuria) hypidrosis is a common attending symptom. In severe diseases where life is threatened, the nose feels cold and dry.

III. Color of the skin. The hair and pigment prevent us from seeing that color of the skin which is caused by the blood and other physiological fluids flowing through it. With the exception of the horse, nearly all white-coated animals have non-pigmented skins. [Horses having white or grey hair coats show pigmented skins, the white-born (albino) horses forming an exception. The parts of the skin which show white markings (legs, forehead) are as a rule not colored].

Chronic discharges from natural openings (the eye, nose, vulva) cause a loss of pigment from the portions of the skin over which they flow.

An injection (reddening) of the skin is only of diagnostic importance when not produced by local diseases of the integument. A diffuse reddening of the skin, namely of the abdomen, neck and between the thighs, is seen in swine erysipelas (Rothlauf). Red spots, often angular in shape, accompanied by swelling of the skin, appearing usually over the neck and along the back, are seen in urticaria in swine.

The skin becomes bluish red (cyanotic) when the blood is heavily charged with carbonic acid gas. It is seen in diseases causing swelling of the glottis, heart diseases, congestion and oedema of the lungs, and in overdriven sheep or swine during hot weather.

Yellow (icteric) discoloration and paleness of the skin will be considered under “Examination of the Conjunctiva.”

IV. Condition of the skin. The skin of a healthy animal
feels *pliable* and *elastic*, and is movable upon its underlying tissues. If a fold of it be drawn out between the fingers, it soon regains its former place when released.

Where the animal is poorly nourished, out of condition, or emaciated from wasting disease, the skin feels *hard* and *leather-like* (sclerosis, induration). [If the sub-cutis has also lost its elasticity, and the skin adheres closely to the underlying parts, and cannot readily be drawn out in folds, it causes a condition that is commonly termed "hide boundness."

In the hide bound animal the *epidermis* is dry and tough, the outer epidermal layer becomes loose and may be easily removed.

The skin is thus coated with a thick layer of scales and the hair filled with dandruff.

The *exhalations* of the skin sometimes have a penetrating *urinous* odor, noted not infrequently from bladder rupture, the contents of the organ being poured into the abdominal cavity. In the ox *urethral calculi* commonly cause this condition.

V. Swellings in, and immediately under, the skin. Diffuse or multiple swellings appearing in or immediately under the skin are of great importance as an aid to the diagnosis of internal diseases which they accompany.

Tumefactions of the skin attend the following morbid processes:

*Œdema of the skin and sub-cutis* (anasarca) is an abnormal accumulation of serum in the connective tissue. It is produced by a transudation of fluid (liquor sanguinis) from the blood into the intercellular spaces. The lymph spaces being clogged prevents the escape of the fluid. *Œdematous swellings are doughy* on palpation, retain finger imprints, and those of a non-inflammatory character are *cold* and *painless*.

*Œdema* can be due to:

a. continued venous congestion, the free circulation of the
blood being interrupted (dropsy from stasis). In such cases a dropsical swelling appears in pendent portions of the body, removed from the heart. The prepuce, in front of the mæ, ventrally along abdomen and thorax, hind limbs, brisket and throat are the favorite seats of these enlargements. Any morbid condition which interferes with the free flow of the blood through the veins, leading to a stagnation in these vessels, tends always to produce edematous swellings. They attend organic heart troubles, chronic pleuritis, pericarditis, and traumatic pericarditis of the ox.

b. a watery condition of the blood (hydræmia) with which occurs an abnormal porosity of the blood vessels. Dropsies due to hydræmia are noted in sheep afflicted with animal parasites, [the lung and stomach worms, Str. contortus, Str. filaria; liver flukes, Dist. hepaticum, being the most common]. Leucæmia and anaæmia are frequently attended with skin dropsies.

c. inflammatory cædema. (collateral cædema) also produces swellings of the skin, but as this is usually local, it is mostly of surgical interest. In one form of anthrax appears a circumscribed, hot, hard, painful tumor on the neck, head, or body—the malignant carbuncle. A local, hot, edematous swelling often betrays the presence of deep-lying inflammation—pus, and is therefore important in diagnosis. In strangles of horses suppuration in unavailable lymph glands is determined by the accompanying cædema of the skin in the region of the throat; in glanders it occurs about the farcy bud; in traumatic peritonitis a hot, doughy swelling appears in the hypochondrium.

In some of the infectious diseases a more or less diffuse, or a multiple inflammatory cædema, becomes manifest: in influenza of the horse the eyelids, scrotum and limbs swell; in purpura hemorrhagica multiple, later diffuse tumefactions occur on the head, prepuce, lower abdomen, and limbs. Leg swellings in purpura are characterized by their abrupt bolster-like, termination.

Emphysema of the skin. Emphysema of the
skin signifies the presence of air in the subcutaneous tissue. Such swellings crackle on palpation and are usually well defined. The contained air can be temporarily displaced by applying pressure to parts of the swelling, but as soon as the pressure is released the space caused by it refills.

Emphysema originating spontaneously is infrequent. It is mostly due to the formation of gas in decomposing blood extravasates or retained abscesses. Spontaneous emphysema is pathognomonic of symptomatic anthrax, black leg, where it appears upon the back, neck, and muscular portions of the legs.

Emphysema occurs most frequently from the inspiration of air from without into the subcutis. The air may enter through a wound in the skin, or may come from some air-containing internal organ. In the first case the air is sucked or pumped into the subcutis through skin wounds which continually shift position during locomotion. Wounds in the neighborhood of the elbow, therefore, produce emphysema of the shoulder and neck. [It is a common practice to treat atrophies of superficial muscles ("sweeny") by inflating the overlying skin with air artificially introduced by a bicycle pump or pipe stem.] In the second case the emphysema of the skin has its origin from an internal organ, usually the lung, the alveoli of which are ruptured. The course followed by the air is as follows: It passes from the ruptured alveoli into the subpleural connective tissue, making its way to the mediastinum, between which folds it continues to the upper part of the thorax, then following the course of the trachea, large blood vessels and esophagus, it escapes from the pectoral cavity through its anterior aperture into the subcutaneous and intermuscular tissues. Rupture of the pulmonary alveoli may result from a destruction of the lung tissue by pus or putrefaction (gangrene). Rib fractures involving the lung, great intra-thoracic pressure from violent coughing, continued bellowing, forced contractions (straining) of the abdominal muscles in bowel, bladder and uterine troubles, may be at the bottom of emphysema of the integument.
Sometimes after rumenotomy or trocaring, gas passes from the paunch through the muscular wound into the subcutaneous tissue. The skin wound having shifted position, the escape of gas to the surface is prevented, hence it collects in the loose connective tissue along the back.

**Diseases of the Skin.**

The following terms are most commonly employed to denominate the phenomena of skin lesions:

1. Spots, are well circumscribed abnormal colorations of the skin.
2. Papules are small cutaneous elevations of solid consistency varying in size from that of a pin head to that of a small pea.
3. Vesicles are elevations of the outer epidermal layer due to the accumulation of fluid beneath. They vary from the size of a millet-seed to that of a pea.
4. Bullæ, (small blisters) are large vesicles.
5. Pustules, are vesicles containing pus, and are therefore colored-yellow.
6. Ulcers, are suppurating wound surfaces which result from necrosis of tissue.
7. Scales (squamae), are epidermic lamellæ which have become detached from the skin's surface.
8. Scabs, or crusts, are dried masses of exudate upon the surface of the integument.
9. Hives, (urticaria, nettle rash), are due to swellings of the papillary bodies, producing well defined evanescent rounded elevations, resembling welts raised by a whip.

I. Non-parasitic Skin Diseases.

1. Alopecia (baldness) is a loss of hair due to some disturbance in the skin's nutrition. It may not be attended by lesion.
2. Blood sweating (hematidrosis) is the spontaneous appearance of blood upon the apparently intact surface of the integument. It is peculiar to Hungarian horses.
3. Prurigo is a papular eruption accompanied by intense itching. Biting and rubbing induce additional lesions.
GENERAL PART OF EXAMINATION.

4. Summer surfeit (papulo-vesicular-eczema) is a nodular eruption occurring usually over the neck and shoulders, leading to a loss of hair. [It is seen mostly during the hot months. This condition is often erroneously attributed to some "disorder of the blood." Its chief cause is neglect of proper grooming and care of the skin of horses.]

5. Fagopyrism is an acute, diffuse, itchy inflammation of the non-pigmented skin of the head, due to grazing on growing buckwheat in bright sunshine. Brain symptoms sometimes complicate the disease.

6. Eczema. In a general way the term eczema designates an exudative dermatitis. It has much in common with the catarrhs of mucous membranes, and like the latter can pass through the varied stages of erythema with desquamation, papule, vesicle and pustule formation and finally squamme. It is very common in dogs, appearing along the back.

7. Foot eczema, produced by potato residue, swill and brewer grain feeding, is a vesicular eczema occurring on the hind legs of the ox. The vesicles rupture soon after formation and their contents dry to thick yellow scabs. The hair of the affected parts stands erect and part of it falls out. In most instances the eczema reaches no higher up the legs than the hock, but may spread to the body or involve the anterior limbs.

II. Skin Diseases Due to Animal Parasites.

The common skin parasites are:

1. Lice or Pediculidae (Hæmatopinus asini, eurysternus, urius, etc.)
2. Bird lice or Mallophaga (Trichodeectes equi, scalaria, etc.)*
3. Louse flies or Hippoboscidae (Hippobosca equina, Melophagus ovis).
4. Ticks or Ixodidae (Boophilus bovis) Texas cattle tick.
5. Fleas or Siphonaptera (Ceratopsyllus serrateceps of dog, Pulex erri- tans of man).
6. Bird ticks or Gamasidæ (Dermanyssus avium, D. gallinæ).
7. Mites or Acarina (Chorioptes symbiotes, horse, ox, goat, etc.) (Psoroptes communis, horse, ox, sheep, etc.) (Sarcoptes equi, canis, suis, cati, etc.) (Sarcoptes mutans of fowl), (Acarus folliculorum or Demodex folliculorum, var. canis, suis, etc.)

[*The common hen louse, Menopon pallidum, is remotely related to the trichodeectes, and resembles them in general appearance. It is said to pass readily to other species of birds, and to trouble horses kept near lousy henroosts..]
**Mange** is a contagious dermatitis due to mites. The principal manges are:

**Fig. 9.**

*Haematopinus equi.*
Blood-sucking Louse.

**Fig. 10.**

*Trichodectes equi.*
Scale-eating Louse.

**Fig. 11.**

*Symbiotes bovis.*
Ventral side

**Fig. 12.**

*Psoroptes communis.*
Ventral surface, Egg in Oviduct.
a. *Symbiotes mange* (foot mange): Favorite seats; in the horse the hind ankles, in the ox the tail root.

These mites live on the skin, produce loss of hair, desquamation of epithelium, and intense pruritis, causing the animal to stamp and kick continually. The mites are \(0.3-0.5\) mm, head broad. The legs which are long, are provided at their ends with bell-shaped suckers.

b. *Psoroptic mange*. Seen in the horse, sheep and ox. Characterized by great desquamation, the appearance of vesicles and papules, the hair or wool being agglutinated by crusts of dried exudate; wool becomes flaky, falls out in patches, intense pruritis. The *psoroptes* is the largest mange mite, being \(0.4-0.7\) mm long, head long, pointed, the three-jointed legs provided with tulip-shaped suckers.

c. *Sarcoptes mange*. Seen in horse, dog, swine and cat, etc. This mite burrows tunnels in the cutis, causes nodules, crust formation, thickening and folding of the skin, pruritis. Most difficult mite to capture for microscopical examination; to obtain material for examination the skin should be scraped to bleeding. Sarcoptes are very small, turtle-like mites measuring \(0.2-0.5\) mm, head horse-shoe shaped, legs short and stumpy.

d. *Sarcoptic mange of fowls* (*Dermatoryctes mutans*). It affects the legs causing "Scaly Feet." The lower, naked portions of the legs becomes coated with calcareous, smeary or honey-like, scaly, thick deposits.

e. *Acarus mange*. Most common in dogs, appearing principally on the eyelids, head, extremities, causing little itching. Skin covered with scales, small pustules, and is thickened and folded. The parasite is vermiform, \(0.2-0.3\) mm, with a long, narrow, jointed body, the anterior portion carrying four pairs of short, three-jointed feet, at the end of each a pointed hook.
III Skin Diseases Due to Plant Parasites.

Ringworm (Herpes tonsurans) is induced by the fungus Trichophyten tonsurans. The disease is characterized by the appearance of small, round, well-defined hairless patches. The smooth skin is covered with grey-colored, asbestos-like crusts. Spontaneous healing begins in the center of the lesion, extending toward the periphery ("ringworm"). Vesicles rarely appear. Most common in the ox. In the crusts and more especially in the hair follicles great numbers of round or ovoid, light-refracting spores can be seen with the aid of the microscope. The spores measure 4μ. Some of the spores are arranged in regular order like a string of beads, others are disposed in irregular groups. The filaments, which may be simple or jointed, show little tendency to branching; their free ends are rounded.

Favus. Rare, but appears in fowls as so called "white comb" (Tinea galli). Small whitish-grey spots come upon the comb which gradually is encrusted by them. In mammals thick, depressed, yellowish brown crusts appear.

IV. Acute Exanthemas.

1. Foot and mouth disease [said not to occur in the United States], is an acute infectious disease of cloven-hoofed animals, characterized by the appearance of vesicles upon the mucous membrane of the mouth, the skin of the coronet, and in the interdigital space. Period of incubation 1 to 3 days. The disease is attended by moderate fever, salivation, diminished appetite, lameness, recumbent position. The vesicles rupture, leaving erosions on the mucous membranes, and dry scabs on the skin. Complications are not infrequent. Prognosis generally good.

2. Sheep pox is a contagious exanthema running an acute course and having a typical character. Incubation 4 to 7 days; artificial inoculation shorter. On the haired portions of the body, around the eyes, nose, mouth, inner surfaces of the legs, appear punctiform reddenings (pimples), later papules. In about six days the papules are covered by vesicles filled with a clear, tenacious fluid (eruptive stage). In the next
few days the contents of the vesicles become turbid, forming pustules (suppurative stage); then drying of the pustules to a solid crust (exsiccativ stage). When the crusts fall off a small depressed cicatrix (pit).

**Fig. 10**

_Urticaria._

remains. During the eruption there is fever, loss of appetite, etc. Course about 3 weeks. Mortality 10 to 50%.

3. **Canadian horse pox.** A contagious pustulous exanthema limited usually to the saddle and harness rests. Period of incubation 2 to 3 days. A few isolated prominences of the size of a half dollar appear, the hair on them is erect and gathered into tufts. The contents of the bullae becomes purulent, erupts, dries to a brownish-yellow solid crust. Caused by a bacillus measuring 2\(\mu\), which admits of staining with fuchsin.

4. **Urticaria** (nettle rash) is a per-acute exanthema which is characterized by its sudden appearance. Tumefacto is from the size of a peppercorn to that of a hand or saucer come upon the neck, head, inner surface of the hind limbs and on the body. They are prominent, flat, soft, warm, the hair upon them standing erect; itching is rare.
V. General Diseases which Affect the Skin.

1. Purpura hemorrhagica (morbus maculosus) is an acute infectious disease (an intoxication) characterized by the appearance in the various organs of the body, of multiple hemorrhagic centers of varied size. In the absence of complications, the disease is unattended by fever. On the mucous membranes of the nasal passages blood spots are seen, more rarely they occur in the conjunctiva and buccal mucous membranes. In the skin and subcutis of the lips, cheeks, and nostrils, appear hard, inflammatory, oedematous swellings from the size of a pigeon’s egg to that of a hand (larger by confluence), causing the head of the horse afflicted to resemble that of a hippopotamus. The extremities also swell, the swellings terminating abruptly at the stifle and the elbow. There is a diffuse edema of the lower abdomen; hemorrhage in the internal organs. Breathing is labored and stentorious from the mechanical obstruction (swelling) to the entrance of air into the upper respiratory passages. There is difficulty in deglutition, colic symptoms, and impaired locomotion. When the disease has existed for several days, the temperature increases. Course atypical, 6 to 21 days. Mortality about 50%.

VI. Acute Infectious Diseases which Affect the Skin.

1. Black leg (symptomatic anthrax) is an acute infectious disease caused by the entrance of a germ through a lesion in the skin, a peculiar emphysema resulting. On the body, shoulder, neck, upper portions of the extremities (never below the knee or hock) appear swellings which are at first hot and painful, but later cold, painless, emphysematous. Incision causes a foamy, fetid fluid to flow out of them. Attending symptoms are high fever, great depression, lameness, dyspnoea. Mortality is high. [Prophylaxis, protective inoculation].

The bacillus of black leg are contained in the discharges from the swellings. They measure 3-5μ long, 0,5-0,6μ broad. One end or the middle is enlarged to receive an ovoid spore which it bears. May be stained by Gram’s method.

2. Malignant oedema (of Koch) appears under the same symptoms as black leg; the swellings are more oedematous than emphysematous.

The bacilli of malignant oedema is somewhat like the bacillus of anthrax, 3-3, 5μ long and 1, 1μ broad. They are mostly united at their ends to form long threads. In the middle of some of the bacilli or at the ends occur spindle or drumstick-like enlargements to receive the ovoid spore. The spore does not accept ordinary stains.

3. Bovine pest (Rind-und Wilder-seuche) is produced by the bac-
terium of hemorrhagic septicæmia and appears in the exanthematous, pectoral, or intestinal forms. On the head and neck appear large inflammatory oedematous swellings, which spread to the mucous membranes of the mouth and throat. The pectoral form is attended by a croupous-hemorrhagic pneumonia with pleuritis, and the intestinal form with hemorrhagic enteritis and swelling of the intestinal viscera. The Bacterium septicemææ hemorrhagicae, like that of contagious pneumonia of swine and of chicken cholera, is o, 6μ long, o, 3μ broad, oval, stains only at the ends, an unstained belt remaining.

4. Examination of the Conjunctiva.

The examination of the conjunctiva serves to determine the quantity and condition of the circulating blood.

Fig. 17.

Method. Avoid all rough and hasty manipulations. Before grasping the eyelid gain the animal's confidence by arranging the foretop and gently stroking the forehead. The right eyelid should be lifted with the fingers of the left hand, the left one with those of the right hand. By means of the thumb the upper eyelid is raised, the index finger then re-
places the thumb, then by gently pressing the everted lid inwardly, the mucous membrane of the upper eyelid and the membrana nictitans become visible. The thumb, which is now free, draws the lower lid downward. The other three fingers may be rested against the zygomatic arch, steadying the hand. (See figure 17).

In the ox a good view of the scleral conjunctiva may be obtained by simply taking hold of a horn and the nose, and drawing the head to one side.

If we wish to arrive at the condition of the blood from an examination of the mucous membrane of the eye, that organ must be free from local irritation. Severe exercise, high atmospheric temperature cause a healthy mucous membrane to appear very red from physiological congestion; local inflammation also produces congestion.

A careful comparison of both eyes will enable us to determine the presence of local inflammation. In healthy animals the color of the conjunctiva is pale-roseate; in the ox paler than in other animals. A few blood vessels are always visible. In the conjunctiva, the boundary between normal and diseased conditions is not sharply drawn, hence practice alone makes one capable of giving a reliable judgment.

I. Color. The color of the conjunctiva is due to the quantity of blood circulating in the blood vessels of the organ and the amount of hemoglobin contained in the blood corpuscles. A pale, anaemic color shows that the animal is either deficient in blood or that the blood does not contain its normal quota of red corpuscles. The color varies from reddish-white to greyish-white or white.

Paleness occurs suddenly:

1. following great loss of blood, internal hemorrhages (liver, heart, large blood vessels etc.)
2. in congestion of blood in the intestines (embolism of intestinal arteries, displacement or torsions of the bowels).

Paleness appears as a chronic condition:

3. in constitutional diseases of the blood making organs (leucæmia).
4. in all chronic diseases which lead to anæmia or hydræmia, glanders, tuberculosis, distomatosis (liver flukes)
parasitic diseases of the stomach and lungs of sheep.

Abnormal redness (congestion). When not due to plethora, a dark red discoloration assumes the following forms: diffuse, ramiform, or spotted and brick red, dark red to muddy (cyanotic).

An abnormal red coloration of the conjunctiva is seen:

1. in congestion of blood in the head (congestion of the brain, inflammation of the brain,) the blood vessels can be observed appearing prominently in the diffusely red mucous membrane.

2. where the free flowing back of the venous blood from the head is impaired, leading to a great distention of the veins: heart diseases, weak heart, pulmonary emphysema.

A diffuse, faded bluish-red discoloration of the conjunctiva is found in conditions leading to an overcharging of the blood with CO2. It is seen in feverish diseases (infectious diseases), and wherever air is prevented from passing freely into the lungs: diseases of the respiratory tract, respiratory muscles, or heart.

Inflammation of the mucous membrane of the gastrointestinal tract in the course of colic, produces a cyanotic conjunctiva; if fever appears it becomes ramiform (a bad sign).

Yellow (icteric) discoloration is best observed on the scleral conjunctiva. It is not noticeable by artificial light. If the conjunctiva is pale (bloodless), the yellow can be more readily appreciated. The shades vary from a mere trace of yellow to pronounced lemon yellow; in most cases combined with congestion. The icteric discoloration is due to the abnormal amount of bile coloring matter found free in the blood serum.

According to the origin of the yellow coloring matter we distinguish:

Hematogenic icterus—originates from a dissolution of the red blood corpuscles, the coloring matter which is set free, remaining in the serum. Hematoidin and Bilirubin come from the hemoglobin. In contagious
pleuro-pneumonia of the horse, influenza, azoturia, and in pyemia icteric mucous membranes are seen.

Hepatogenic icterus—a stagnation of the bile in the gall ducts from occlusion of the same (icterus of absorption), or from a swelling at the opening of the ductus choledochus preventing the flowing out of bile into the duodenum (icterus of stasis) can produce hepatic jaundice.

Icterus is most commonly due to an occlusion of the ductus choledochus. Tumors (carcinoma in dogs) may compress the gall ducts, and toxic substances can so act upon the liver as to cause icterus.

Hepatogenic icterus is characterized by the absence of bile pigments in the feces (which are of light color,) and their appearance in the urine. Severe icterus (icterus gravis) is associated with mental depression and slow pulse.

II. Moistness of the conjunctiva. When the conjunctiva is abnormally moist the membrane assumes a peculiar glistening appearance; in febrile diseases and in severe colics the membrane is comparatively dry.

III. Hemorrhages. Hemorrhages appearing in the conjunctiva during the course of internal diseases are only punctiform when the blood has escaped into the tissue through small ruptures in the vessel walls (hemorrhage per hexin). These foci are punctiform, spotted, (petechia, ecchymosis). Seen in purpura hemorrhagica, severe septicæmia, or pyæmia; great anæmia, pernicious anæmia.

IV. Swelling. Swellings of the conjunctiva usually are diffuse and may occur in both eyes. They are due to a serous infiltration of the mucosa and sub-mucosa. If of an inflammatory character they are hot and painful. This condition finds its best development in influenza of the horse, the greatly swollen, glassy mucous membrane protruding from between the half closed lids. It is seen in contagious pleuro-pneumonia of the horse, malignant head catarrh of the ox, bovine pest, anthrax, dog distemper, chicken cholera.

A non-inflammatory swelling of the conjunctiva is seen in anæmia, cachectic diseases of sheep; from liver flukes, lung and stomach worms.
In the course of chronic diseases of the stomach and intestines a slight swelling of the conjunctiva, attended with a washed-muddy discoloration, appears.

**V. Discharge from eyelids.** Although mostly due to local diseases, some of the infectious diseases have discharges from the eyelids constantly present. The discharge is either *bilateral* (from both sides) or *unilateral* (from one side only). Bilateral discharges are seen in: malignant head catarrh (with keratitis), bovine pest (no keratitis present), dog distemper, fowl cholera, influenza. (Swelling shuts off the tear ducts.) Unilateral discharges occur: in continued chronic nasal catarrh, a symptom of glanders, chronic nasal or sinus catarrh. [In all animals showing unilateral discharge from the eyelids, especially when the discharge is copious, a careful examination for foreign bodies should be made.]

5. **Bodily Temperature.**

The internal temperature of the body is maintained, with slight variation, at a definite elevation by means of an especial regulating apparatus. The production of heat in the body and the loss of heat from the body are kept equal. If the temperature varies from the normal, and this variation be preserved for a time, a disturbance due to disease is affecting the regulatory apparatus.

The determination of the internal temperature is of great importance in the diagnosis of disease, for each deviation from the normal is to be considered a symptom of considerable moment. In all diseases affecting internal organs, the measuring of the temperature is imperative.

**Method of examination.** Formerly the temperature was approximated by laying the hand upon different parts of the body, namely the nose, ears, horns, extremities, or by inserting the fingers into the mouth. Such methods require long practice before a reliable estimate can be obtained,
and they are always deceptive. Only in exceptional cases are
they now in vogue. The temperature is most accurately
measured with a thermometer, graduated in degrees and
tenths of a degree. [Except in America, England and perhaps
one other country the Celsius (centigrade) thermometer is in
common use. It is graduated into 100 degrees, and these sub-
divided into tenths of a degree. In this country the Fahren-
heit thermometer is generally u-ed. It is graduated into 212
degrees, each degree being subdivided into fifths. Our prefer-
ence for this latter instrument is largely traditional, and it is
being displaced by the centigrade, which is now almost
universally employed in scientific work.

The following simple formula will indicate how readily
the Celsius scale may be converted into the Fahrenheit scale
and vice versa:

Fahrenheit\(=9\cdot5 \, C + 32\),
Celsius\(=5\cdot9 \, (F-32)\).

For veterinary practice a maximum thermometer should
be used, preferably a tested or compared instrument. The
thermometer should be inserted full length into the rectum,
which gives the best results, though in exceptional cases the
vagina is chosen.

We should, of course, guard against being kicked by the
animal, and exercise care that the instrument does not break
and injure the mucous membrane. Before introducing the
thermometer, the column of mercury should be shaken down.
The use of water, saliva or oil facilitates insertion. We
should allow the instrument to remain in the rectum from
three to five minutes.

Taking the bodily temperature once daily is of great
value during the course of an internal disease; in important
cases the temperature should be registered twice a day (8 A. M.
and 5 P. M.). After diagnostic inoculations (tuberculin,
mallein), especially during the critical period, the temperature
should be recorded at least every two hours. Thermometry
is of great diagnostic importance during an outbreak of an in-
fec tious disease, the elevation in temperature being often the
first symptom shown. By taking the temperature once daily (best at evening), the infected ani-
mals may be determined before further symptoms of disease develop; [influenza, contagious pleuro-pneumonia, swine plague or hog cholera, Texas fever].

I. The Normal Temperature. The normal temperatures of the different animals are as follows:

- horse..........37.5—38.5° C. (99.5—101.3° F.)
- ox..............38.0—39.0° " (100.4—102.2° " )
- sheep ..........39.0—40.5° " (102.2—104.9° " )
- goat..........39.0—40.5° " (102.2—104.9° " )
- hog..........38.0—40.0° " (100.4—104.0° " )
- dog ..........37.5—39.0° " (99.5—102.2° " )
- fowls......41.5—42.5° " (106.7—108.5° " )

The temperature will vary a few tenths of a degree in the same species, and slight variations may occur in one and the same animal within a single day. This latter variation may amount to 1° C. (1.8° F.). When the organs (muscles, glands) are active a slight rise in temperature takes place, when at rest a slight sinking follows. High atmospheric temperatures or warm stables, inasmuch as they cause a diminishment of radiation, tend to accelerate the temperature. As a rule the temperature is lower in the morning than toward evening.

II. Fever. Although the character of fever is not expressed entirely by elevation of temperature, we have become accustomed to associate high temperature and fever, using the terms as if synonymous. As a matter of fact, the increased temperature is only one of the characteristic and most readily available symptoms of the complex phenomenon called Fever. As a rule, however, there is a direct relationship existing between the height of the temperature and the degree of development of the fever. At times in the ox, the increase of temperature, as measured by the thermometer, fails to correspond with the degree of fever, which can be appreciated by the remaining symptoms.
Besides mere increase in temperature, the following phenomena attend fever:

1. **Chill.** When the temperature of the body rises very rapidly the peculiar symptoms of chill are shown: pronounced trembling of the muscles, which can shake the whole body, arched back, erect hair coat, cold skin. Chill is not a constant symptom of fever, occurring only in certain infectious diseases, such as anthrax, septicemia, malignant head catarrh. It is further seen in animals reacting to tuberculin or mallein.

2. **Acceleration** of the pulse and respirations take place more slowly than the increase in temperature; and they do not bear the same relationship to the temperature in all fevers. The higher the pulse frequency, the more serious the fever, the pulse becoming weak and the artery soft.

3. **Loss of Appetite** and impaired digestion. In fever the secretion of the digestive juices is lessened, peristalsis suppressed, (constipation), thirst increased.

4. **Nervous depression.**

5. **Albuminuria.**

**III. High Normal Temperature.** Although the variations in the normal temperature of a given animal are confined to narrow limits, when the temperature exceeds these limits we are not always justified in assuming the presence of fever. The physiological functions of the organs can momentarily become sufficiently accelerated to produce a degree of temperature in excess of the usual normal one. The appearance of concomitant symptoms or repeated recording of the temperature will generally decide whether fever be present or not. In doubtful cases we speak of high normal temperature.

The following temperatures may be safely assumed to indicate fever:

- In the horse a temperature of $39.0^\circ$ ($102.2^\circ$ F.) and over.
- In the ox $40.0^\circ$ ($104.9^\circ$ F.)
- In the dog $39.2^\circ$ ($102.5^\circ$ F.)

In the ox and dog fever is often present without a rise of
temperature. In such cases we must depend upon the surface temperature and the other symptoms of fever present.

Generally the height of the temperature expresses the height of the fever. Four degrees of fever are distinguished, which for the horse and dog are as follows:

1. **mild fever** 38.5°—39.5° C. (101.3°—103.1° F.).
2. **moderate fever** 39.5°—40.5° C. (103.1°—104.9° F.).
3. **high fever** 40.5°—41.5° C. (104.9°—106.7° F.).
4. **very high fever** or **hyperpyretic temperature** 41.5° C. (106.7° F.) and over.

Usually in the horse even in the most severe infectious diseases, the temperature does not exceed 41.7° C. (107.0° F.); only exceptionally, in tetanus, contagious pleuro-pneumonia, and influenza, is this high mark passed. The highest temperature is carried by fowls, namely 43.5° C. (110.3° F.). [In cases of "heat stroke" in horses an hyperpyretic temperature may reach 110.0° F. See also note on swine temperature].

During a single day a feverish temperature does not remain constant, but agreeing with the variations of the normal temperature, is lower in the morning than toward evening—the so-called morning *remissions* and evening *exacerbations*.

Recording of the variations in temperature which occur during the course of a disease is also of great importance. If the temperature is measured at a certain time daily and the record expressed in a graphic manner, the so-called fever curve is obtained. From the fever curve is recognized the type of fever present.

In veterinary medicine the following types of fever are important:

1. **continued** fever, daily variation less than 1° C. (1.4—5° F.).
2. **remittent** fever, daily variation over 1° C.
3. **intermittent** fever, periodical temporary fall to normal temperature.
4. *atypical* fever is one having no regular character.

In the course of most infectious diseases, three stages are distinguished, according to the course of the fever, viz.:

1. *stage of increasing temperature* (stadium incrementi).
2. *acme*, temperature at its highest, (fastigium).
3. *stage of falling temperature*, (stadium decrementi).

A rapid fall of temperature (within 1–2 days) is called *crisis*, a gradual decline, *lysis*.

According to duration we distinguish: *ephemeral* (one day), *acute* and *chronic* fevers.

**IV. Subnormal temperature.** Like the high normal, the subnormal temperature may be physiological. Further, it may come from the fact that the sphincter ani is relaxed, or that the thermometer has not been inserted deep enough, or that the rectum is filled with feces, or that defecation takes place just before or during the insertion of the instrument.

A sub-normal temperature due to disease is uncommon. It is seen to occur, but not constantly, in parturient paralysis, certain gastro-intestinal diseases of the dog, anæmia, hemorrhage, *icterus gravis*. A subnormal temperature is most frequent in fatal diseases just before death (temperature of collapse).

**V. Temperature of the skin.** The thinner and more vascular the integument and the finer the hair coat, the warmer the organ feels. Exposed surfaces of the skin feel cooler than more protected, covered parts. The ears and extremities, therefore are normally colder than the rest of the body.

The surface temperature is measured by laying our hands upon the skin. During fever the distribution of the bodily heat is often irregular, therefore it is not uncommon to find one leg cold while its fellow may be abnormally hot; in fever in the ox, the horns are sometimes hot and cold alternately. The taking of the surface temperature is only of value in the ox and dog, the use of the thermometer being more reliable in the other animals.
The temperature of the skin is elevated in fever and after exercise; it is diminished usually when the internal temperature sinks as in parturient paralysis, collapse. In the chill stage of fever the skin also feels cold.

**General Infectious Diseases.**

**Septicemia.** Nearly all forms of so-called "Blood Poisonings" are designated by the collective term, Septicemia. Symptoms: suddenly appearing fever, often accompanied by chill; fever of the continued type; mucous membranes highly reddened, often icteric, frequently ecchymosed. Very rapid, small pulse. Food and drink refused; fetid diarrhea. Great mental depression, blank countenance, eyes sunken. Acute or per-acute course.

**Pyemia** is a general disease due to pus cocci gaining access to the blood, and is characterized by multiple, secondary abscess formation (pyemic metastasis) in the various organs, lungs, liver, kidneys, brain, joints, etc. Diagnosis is easy when primary abscess is available; otherwise it is difficult. As each new abscess forms the temperature increases, therefore it is fever of intermittent type. Mucous membranes are congested, icteric. Pulse is continued high. Course subacute.

**Anthrax** is an acute infectious disease due to the Bacillus anthracis. Begins suddenly with high fever; tendency toward hemorrhages from mucous membranes. In the ox and sheep the course is often apoplectic; when course is acute it lasts 1-3 days. Brain symptoms, convulsive twitchings of muscles, rapid pulse, dyspnoea, loss of milk, are symptoms sometimes seen. In horse, colic symptoms occur. Formation of anthrax carbuncle in skin is not rare in the horse. In hog, symptoms of severe laryngo-pharyngitis with swelling predominate. Diagnosis is positive only after finding bacilli under the microscope. An anthrax slide is made as follows: A thin layer of blood or spleen pulp is smeared over a slide, passed three times through the flames of a Bunsen burner, then covered with a 2% watery solution of safranin and allowed to boil by holding over a Bunsen flame for a few moments. Wash and examine.

The anthrax bacilli are from 1 to 2 times as long as the diameter of a red blood corpuscle, and are composed of from 2 to 8 bacterial cells, which are stained reddish brown on the slide. Each bacterial cell is
cylindrical, slightly longer than broad, appearing almost square in form. The ends are plane or somewhat convex. The bacterial cells are surrounded by a gelatinous capsule, which is stained yellow in the preparation, and which joins the cells together to form the bacillus. The capsule is bounded by a dark line. If the bacilli come in contact with one another they unite, their capsules blending together.

Influenza. An acute, infectious disease of the horse, very easily transmitted. Period of incubation 5 to 7 days. First symptom is a rise in temperature which continues 3 to 6 days, then crisis. Great debility, slow gait, staggering, great mental depression, head held down or rested on manger, eyelids and conjunctiva swollen, hot, painful, photophobia. Pulse at first strong, little affected, later accelerated. Loss of appetite, diarrhoea in about 3 days. In later stages cold, painless, oedematous swelling of the extremities. Mortality 4%.

Swine Plague and Hog Cholera. Infectious diseases of swine, caused by bacilli which enter the body through the respiratory tract (swine plague of Smith), or via respiratory tract or mouth— with food and water—(hog cholera of Smith). Period of incubation 4 to 21 days. Young pigs most predisposed. One attack produces immunity in most cases. Symptoms: apoplectic form; die very suddenly or after a few hours illness (beginning of an outbreak). Usual form: fever, temperature 107°-108°F.; appetite impaired, tremblings of muscles, unwillingness to move, stupid, dull, hide in litter. Bowels at first constipated; later diarrhoea. Eyelids filled with mucus. Respiration accelerated, labored; painful, frequent cough. On pendent parts of body skin is reddened, congested; eczematous eruptions, ulceration of skin. Rapid loss of flesh, unsteady, tottering gait. Death within 48 hours to 2 weeks. Mortality 20-100%.

Texas Fever. An infectious blood disease of the ox caused by a protozoon (Pyrosoma bigeminum) which enters and destroys the red blood corpuscles. The disease is spread by the cattle tick, Boophilus bovis, the younger generation of which carries the protozoon. Period of incubation 13-90 days after exposure to tick-infected places. Symptoms: fever (104-109°F.), unnatural recumbent positions and standing attitudes; animal is dull, stupid; in some cases shows vicious tendencies; horns, ears, and hoofs are hot. Pulse is rapid; dyspnoea; constipation, excreta tinged with bile. Visible mucous membranes icteric. In later stages urine red. Ticks of various size to be found on escutcheon, inside of thighs, base of udder or scrotum. Little blood flows from intentional wounds. Characteristic post mortem changes. Duration 3 days to several weeks. Mortality 20-90%.

Fowl Cholera. Period of incubation 1 day. Apoplectic death common. Great exhaustion, staggering, foamy mucus discharged from bill, dyspnoea with respiratory sounds, loss of appetite, diarrhoea, bacilli as in Wild-und Rinder-seuche (wild and cattle plague).
B. The Special Part of the Examination.

6. Circulatory Apparatus.

An examination of the circulatory apparatus is of importance not only to diagnose those maladies which affect the organs carrying the blood, but also from the fact that all general or infectious diseases of a serious character influence more or less greatly the circulation.

A methodical examination of the organs carrying the blood includes:

1. taking the pulse.
2. noting the condition of the peripheral blood vessels.
3. examining the heart.

I. Pulse.

The pulse is felt with the fingers, which may be gently rested upon any of the superficial arteries having bone or other hard tissue under them. In the horse and ox the sub-maxillary artery is most commonly used, in the latter animal the artery is easily felt on the lateral side of the jaw bone. Other arteries which may be used to take the pulse are the radial, plantar, temporal, transverse facial, and coccygeal. In the dog, sheep, goat, and cat the femoral artery is most available. In dogs and cats the brachial artery can be felt on the medial surface of the humerus, just in front of and above the elbow. In the hog and fowl the pulse can not usually be felt, hence the heart's beat is used.

a. The Normal Pulse. From a clinical standpoint the 1) frequency, 2) rhythm, and 3) quality, are of importance to consider in examining the pulse.

1.) Normal frequency. By the frequency of the pulse we mean the number of blood-waves (beats) felt in a minute's time. There is a great variation in the normal frequency,
not only in the different species of animals, but also in animals of the same kind. Many physiological conditions have great influence upon the pulse-frequency: size, age, sex, race, atmospheric temperature, time of day, prehension or digestion of food, exercise, excitement, are all factors.

Large animals carry a slower (less frequent) pulse than small ones; adults slower than young; females higher (more frequent) than males; well bred individuals, quicker than mongrels; in summer the pulse is higher than in winter; in the morning slower than toward evening; excited animals show a more rapid pulse than animals standing at perfect rest. In nervous animals (horses and dogs) the act of taking the pulse often increases its frequency.

Taking these physiological variations into consideration, the following is the average pulse-frequency for the different animals.

1. horses ........................................... .... 28—40.
   colts, two weeks old ........................... -100.
   " four weeks old ......................... - 70.
   " six to twelve months old .. 45—60.
   " two to three years old .......... 40—50.
2. asses and mules ..................................... 45—50.
3. bovines ........................................... 40—80.
4. sheep and goats ................................... 70—90.
5. swine ............................................. 60—100.
6. dogs ................................................ 60—120.
7. cats ............................................. 110—130.
8. fowls ............................................. 120—160.

2.) Normal rhythm. By the rhythm of the pulse we mean that the individual pulse-beats are separated by intervals of equal duration. In large animals, at perfect rest, the pulse is usually rhythmic, but in small animals, especially dogs and swine, an arhythmic pulse is not exceptional. In mules and asses it is also often arhythmic.

3.) Quality. The individual pulse-waves should be of equal volume, i.e., the beats should be of uniform fullness,
alike (puls. aequalis). Depending upon whether the quantity of blood circulating in the arteries is great or small, we distinguish a large pulse (puls. maguus) and a small pulse (puls. parvus), or the artery is spoken of as full or empty. According to the force of the beat a strong and a weak pulse is distinguished. If the artery is tense, the pulse is hard (puls. durus); if relaxed, soft (puls. mollis).

![Normal pulse of horse.](image)

The pulse quality varies in the different animals; the normal volume, force and hardness can be better appreciated through long practice. In the horse the pulse is full, strong and the artery is not very tense. In the ox the pulse is smaller, not so strong, the artery tense, feeling to the finger, under which it rolls, like a rubber tube. In small animals the pulse is rapid, strong and hard; in dogs often arhythmic.

**b. Abnormal Pulse.** The pulse of an animal suffering from disease will vary from the normal in frequency, rhythm, and quality. As far as frequency is concerned the pulse may be too rapid (puls. frequens, accelerated pulse), or too slow (puls. rarus).

The *pulsus varus* is very uncommon. It most often accompanies brain diseases attended by great depression (chronic and sub-acute hydrocephalus, tumors in the brain), icterus

![Slow pulse of horse.](image)
gravis, and poisoning from alcohol or lead. In the horse at times it is seen in gastro-intestinal affections with loss of appetite, probably due to some alteration in the sympathetic nerve.

The *pulsus frequens* is very common in disease. A very
rapid pulse, though characteristic of no special disease, is always a sign that the parenchyma of the heart is affected, hence in severe diseases it is an index to the heart's strength. Rarely in the horse does the pulse frequency exceed 80 beats per minute; if it exceed 100, the prognosis is unfavorable. In the ox a pulse of 100, and in the dog one of 120-150 denotes severe illness.

An abnormally accelerated pulse occurs:

1. in all severe diseases, especially when attended by fever. The frequency of the pulse, however, does not always bear the same relationship to the height of the temperature; whether the pulse be accelerated or not depends upon the fever's affect upon the heart, which differs with the disease present. In contagious pleuro-pneumonia of the horse, septicaemia, anthrax, and severe inflammations of the bowels and peritoneum, the pulse rate corresponds to the height of the fever; in influenza and in strangles of colts, the acceleration of pulse is not marked, compared with the temperature.

2. in painful conditions (severe injuries, fractures of bones abscess in hoof, etc.).

3. in mental excitement (fear, anxiety).

4. in severe hemorrhage.

A bnormal rhy th m. When the rhythm of the pulse becomes abnormal the pulse is either irregular or intermittent.

The abnormal irregular pulse is due to lack of innervation of the heart, as well as to exhaustion of the organ. If the pulse of the horse exceeds 90 it is usually irregular. Irregularity is also observed in valvular diseases of the heart, and in myocarditis.

The pulse is intermittent when a beat fails now and then. When regularly intermittent, a certain beat can not be felt, as for instance, every fourth or fifth pulse wave; when irregularly intermittent there is a lapse of pulse which does not occur between any certain beats. Sometimes the heart's beat is synchronous with the intermittency of the pulse; at other times the heart's beat is normal, the intermittency occurring only in
the peripheral vessels. To determine this the radial pulse and heart's beat can be compared.

The intermittent pulse is commonly physiological, and seen in perfectly healthy horses and dogs, where it disappears after exercise. Pathologically it appears in chronic hydrocephalus ("dummies"), severe gastric troubles, and during convalescence from infectious diseases which have occasioned high pulse (contagious pleuro-pneumonia of the horse).

Quality. The quality of the pulse will vary normally. The force and volume of the pulse is materially affected in disease, the small, empty pulse being a common abnormality. Depending upon the degree of weakness and volume, many special types of pulse are distinguished. If the beat is so weak as to cause simply a vibration to pass through the empty-feeling arterial walls, we speak of a trembling pulse (puls. tremula). When the pulse is very weak and the artery feels empty, a thread-like pulse (puls. filiformis) is present. In very severe fatal diseases the beat cannot be felt, and the pulse spoken of as imperceptible (puls. insensibilis).

The tonus of the pulse is due to the force of the heart's action and the tension of the arterial walls. The pulse is hard—can not be suppressed easily by the finger—in acute brain diseases, tetanus, and great pain. If the pulse is hard and small we speak of it as wiry, characteristic of inflammations of serous membranes, and seen in severe colics, tetanus, and chronic nephrites attended with hypertrophy of the heart.

The pulse is unequal when the pulse waves are not of equal size, small waves occurring in the intervals between larger ones. An unequal pulse is an important symptom of the
heart's weakness and is usually combined with irregularity; it is further noted in valvular diseases of the heart.

When the pulse wave is very short, the sudden expansion of the artery being followed by an equally swift contraction of the same, we speak of a "jumping" or quick pulse (*puls. celer*); if the pulse wave is long-drawn-out, we speak of the "tardy" pulse (*puls. tardus*). The hopping pulse is seen in a degree of cardiac hypertrophy (left heart). An insufficiency (defect) of the semi-lunar valves sometimes develops an exquisite jumping pulse, part of the great volume of blood forced into the aorta by the hypertrophic left ventrical, regurgitating. It is remarkable that a jumping pulse may attend heart's weakness; it is the result of short spasm-like contractions of the heart; the pulse is weak and the artery empty. The *pulsus tardus* is characteristic of stenosis of the aorta and is a small pulse.

![Dicrotic pulse of horse.](image)

The *dicrotic* pulse is characterized by small beats following larger ones, forming a double pulse wave. It comes from a diminishment of arterial *tonus* combined with heart's weakness; it occurs, therefore, following long continued fever, in all forms of anaemia, and is not as well developed in the animal as in the human being.
II. Examination of the Peripheral Blood Vessels.

Arteries. A strong pulse attending wasting disease and emaciation calls for an examination of the small superficial arteries. An abnormally strong pulsation in the peripheral arteries of small caliber is visible in the horse in the branchings of the external maxillary artery.

It appears in hypertrophy of the left ventricle especially when the bicuspid valves are defective.

Veins. The state of distention of the veins is of primary interest. The veins become prominent after any acceleration of the heart’s action in thin-skinned, fine-haired horses; the condition, which is physiological, being a temporary one. A permanent distention of the veins is pathological, and is due to an obstruction of the free flow of blood to the right heart. It is most plainly visible in the jugulars and their plexus on the head, other superficial veins (external thoracics, milk veins, veins of the extremities) showing it less on account of the oedema usually accompanying the condition.

The jugulars can be distended to the size of the human wrist, or even the arm, appearing as great, round strands. The veins of the conjunctiva can also be distended, being recognized as ramiform, often contorted, bluish strands in the mucous membrane.

The veins are generally distended:

1. in valvular disease (tricuspid). It is usually secondary, but in the ox mostly primary;

2. in chronic pulmonary diseases interfering with circulation: emphysema;

3. in diseases of the heart’s muscle, the organ having become so weak that it is unable to handle the quantity of blood:
traumatic myocarditis of the ox.

4. from excessive intrathoracic pressure upon the heart and large blood vessels: tympanitis, pleuritis, pericarditis traumatica of the ox.

**Pulsation in veins.** Besides being distended, veins can show pulsation under some circumstances. Synchronous with the respirations, and independent of the heart's action, a slight swelling of the jugulars occurs during the act of expiration, to fall again at inspiration. A so called jugular pulse is normal in the ox for the following reasons: The jugulars and anterior vena cava in this animal are comparatively large. The continual flow of the venous blood into the right heart suffers during the systole of the right auricle, which slightly precedes that of the ventricle, a momentary interruption, the blood congesting in the anterior vena cava and jugulars, causing a brief distention of the jugulars, simulating a pulsation. It is therefore not an active pulsation, but merely a passive undulation due to a regurgitation of the blood in the form of waves. The presystolic appearance of the pulse movement characterizes it, therefore it should always be compared with the arterial pulse. The collapse of the vein is synchronous with the arterial pulse.

The undulation of the jugular vein is intensified in the ox and becomes apparent in other animals when the above cited condition prevails, induced by a morbid congestion of the blood at the heart. In the horse the venous pulse is seen near the aperture of the thorax (lower portion of the neck).

A true (positive) venous pulse is pathological. It is coincident with the heart's systole, and is produced by a defective closing of the atrio-ventricular valves, the blood regurgitating into the auricle. True venous pulse is a characteristic symptom of tricuspid insufficiency. The valves in the jugulars do not prevent the flowing back of the blood, as they are commonly not well developed, and if the vein be greatly distended they cannot close the lumen of the vessel.
III. The Heart.

The heart is examined by palpation, percussion and auscultation.

Anatomical. In all domestic animals the heart lies in the ventral portion of the thoracic cavity between the third and sixth ribs, in the dog extending to the seventh rib. The great mass of the organ (3.5) lies to the left of the median line, so that it approaches nearer the left thoracic wall than the right one. It does not occupy a perpendicular position, but an oblique one directed from the right, in front and above to the left, backward and downward, the left side of the apex reaching the chest wall.

Horse. The base of the heart lies below the upper half of the height of the chest cavity, resting against the thoracic wall, between the 4th and 5th intercostal space. The point of contact occupies a surface of about 10 cm high and 6.8 cm broad. (See Fig. 25.)

Ox and small ruminants. The heart is smaller and does not extend quite as far back as the 6th rib, its base, however, extends to the medial line of the chest. Between the 4-5 ribs it comes in immediate contact with the thoracic wall. (See Fig. 26.)

Dog. The heart is of rounder form and lies very obliquely, touching the chest wall along a narrow strip from the 4th to the 7th ribs. The apex is below the 7th intercostal space. (See Fig. 27.)

Palpation of the heart's region. The beat of the heart can be felt by laying the flat of the hand over the cardiac region. Inasmuch as the aconcent musles partly cover the region, the hand should be placed between them and the chest wall. In the depths a dull thud will be felt, produced by the thumping of the heart against the chest wall. The beat is due to a contraction of the heart's muscles which causes a slight torsion of the organ to the left, bringing the left side, not the apex, in contact with the wall of the chest. The beat can best be felt just at the 5th intercostal space at the union of the ribs to the cartilages of the sternum. The force with which the beat can be felt depends upon the condition of the animal as to flesh, it being more plainly marked in thin animals, and just after severe exercise or excitement. Only in the dog can the heart's beat be felt normally on the right side.

The force of the heart's beat can be increased or diminished. When the force of the beat is much increased a palpitation of the heart is spoken of. It occurs:

1. in hypertrophy of the heart (here combined with strong pulse).

2. in heart's weakness, the muscles of the organ under-
going spasm-like contractions incapable of properly propelling the blood to the periphery, the pulse being small. The condition is seen in acute myocarditis, endocarditis and pericarditis.

3. where the lung between the heart and the chest wall becomes thickened.

The heart's beat is weakened:

1. where the force is enfeebled from degeneration of the heart's muscle.

2. where the heart is crowded away from the chest wall by accumulations of exudate in the thoracic cavity (pleuritis, pericarditis) or in some cases of pulmonary emphysema.

Percussion of the heart. Except in very thin animals (horses) the percussion of the heart is of no great value in the diagnosis of disease, the reason being that with the percussion hammer we are unable to determine the boundaries of the organ, the adjacent lung tissue so modifying the sound that the going over of the *dull* sound of the heart's percussion to the *full* sound of the lung's is a very gradual one.

**Horse.** In the horse, under favorable circumstances, in the region of the 4th and 5th intercostal space a zone of dullness about the size of a hand can be brought out by percussion. Its boundaries, however, are generally indefinite.

**Ox** Although the chest walls are thinner in this animal, the heart is covered more by the lungs than in the horse.

**Dog.** A narrow horizontal line of dullness between the 4th and 7th ribs can be determined by vigorous percussion.

The zone of cardiac dullness is increased in hypertrophy of the heart and where fluids collect in the pericardium; tumors and thickenings of the lungs also induce it.

The zone of cardiac dullness is sometimes decreased from pulmonary emphysema.

A tympanitic tone on percussion over the cardiac region is obtained in traumatic pericarditis of the ox, gases of putrefaction accumulating in the pericardium.

The percussion of the cardiac region causes the animal pain in pleuritis and pericarditis.
The Auscultation of the Heart.

Method. The auscultation of the heart may be practiced by placing the right ear just behind the left elbow, the leg being drawn forward. Small animals may be laid upon the table and the phonendoscope used.

Physiology. In the cardiac region and in the neighborhood of the same, we hear at each action of the heart two tones. One of these tones appears at the moment the organ contracts (systole), and the second tone, which quickly follows the first, at the dilation of the organ (diastole). The second tone follows so closely the first one that it is difficult to differentiate between them, except in animals which carry a pulse below 60. In animals which have rapid pulse it may be necessary to compare the pulse at a peripheral artery with the heart's beat.

The origin of the heart-tones is still subject to dispute, the authorities not agreeing.

[The first heart-sound (the systolic) is caused by the contracting muscles of the organ and the closing of the atrio-ventricular valves. The second sound is produced by the closing of the semi-lunar valves.]

The first sound in our domestic animals is duller, deeper, more prolonged and usually louder than the second one, which is short, not so deep, well defined (sharper), not so loud, and at times slightly metallic. There is a great variation in the sound produced by the heart in the different animals, and even in animals of the same species, the sounds being in one case sharper (more metallic) and in another deeper and duller. The thickness of the chest walls is also of influence, in animals with well-muscled chests the sounds are seemingly more muffled, duller. By pronouncing the syllables lub-dub one can mimic the sounds of the heart.

\[
\begin{array}{cccc}
| I & II & I & II \\
| lub & dub & lub & dub \\
\end{array}
\]

Change in Heart-Sounds Due to Disease.

Both sounds are increased in:

1. hypertrophy of the heart, the valves remaining intact. (idiopathic hypertrophy).
2. anaemias.
3. a thickening of the lung tissue around the heart, producing a better conductor of sound.
The second sound only is increased:
when the arteries are greatly distended, not infrequently
the result of a congestion of the pulmonary circulation com-
bined with hypertrophy of the heart.

Both sounds are weakened when the normal heart becomes
enfeebled through disease of its parenchyma, or where the
hypertrophic organ is exhausted.

Metallic tones occurring during systole are very common in
anaemic animals. In traumatic pericarditis of the ox, the per-
icardium containing gas, a loud metallic tone is heard at each
systole when the heart-muscle is still vigorous. Sometimes
the sound can be plainly heard the distance of several paces
from the affected animal.

A splitting | --- | --- | or doubling | --- | --- | of the
heart sounds, the condition of the circulatory apparatus being
otherwise normal, is of no significance. Commonly the first
sound is preceded by a short tone | --- |, which is pro-
duced by the contracting and unusually well-developed
auricle.

Heart bruits. Heart bruits are abnormal sounds
and are therefore pathological. They are caused by the sound
producing parts of the organ vibrating for too long a time.
Endocardial bruits and pericardial bruits are distinguished.

a. Endocardial bruits (noises) come from within the
heart and are closely connected with the heart sounds. We
can distinguish, therefore, systolic bruits and diastolic bruits, de-
pending upon whether they occur at the first or second sound.
If the bruits are produced by anatomical changes of the heart
itself, they are called organic, otherwise inorganic noises.

The organic or endocardial heart bruits are caused either
by a narrowing (stenosis) of the atrio-ventricular or arte-
rial openings or by alterations on the valves preventing them
from closing properly (insufficiency). They form most
valuable symptoms in the diagnosis of heart diseases.

In stenosis the bruit occurs at the moment the
blood passes the contracted orifice, the walls of
which are set in vibration. If the stenosis involves the atrio-
ventricular opening the bruit occurs at diastole, if in the arte-
rial openings, at systole.

In insufficiency the bruit occurs at the mo-
ment at which the valves should close. In con-
sequence of their inability to close a regurgitation of the blood
takes place, which produces a renewed vibration of the valves,
and gives a bruit. If the insufficiency involves the atrio-ven-
tricular valves, the bruit occurs at systole; if the semi-lunar
valves are insufficient the bruit appears at diastole

The character of the bruits is varied, they can be buzzing,
blowing, hissing, humming, sawing, rattling, long or short
tones Insufficiency bruits are generally softer than those due
to stenosis. Heart bruits are made more pronounced by an
acceleration of the heart's action, therefore the patient should
be exercised before examination.

Systolic bruits | ~ ~ ~ | are characteristic of

| insufficiency |
| of an atrio-

ventricular
valve.

| stenosis of |
| an arterial

opening.

Diastolic bruits | ~ ~ | are characteristic of

| stenosis of |
| an atrio-

ventricular
opening.

| insufficiency |
| of a semi-

lunar valve.

Although the bruits originate in different parts of the
heart, the exact point of origin cannot be determined by
auscultation. In the horse and dog valvular lesions have their
seat most commonly in the left heart, rarely are they primary
in the right heart. In the ox valvular diseases of the right
heart are more frequent than of the left one. The atrio-
ventricular valves are more commonly diseased than the semi-
lunar.
Contrary to the endocardial, organic bruits, the inorganic or anaemic bruits occur without that any discernible anatomical alteration appears at the orifices or valves of the heart. Inorganic bruits are systolic, soft, blowing and not constant. They tend to disappear and reappear again. Their origin is not well understood. They are nearly always noted in anaemic animals.

It is very important to distinguish between organic and inorganic heart bruits, but in practice this is often very difficult. As a rule, soft, systolic bruits should be very carefully estimated. Organic heart bruits are always accompanied by hypertrophy and often alteration of pulse, and frequently venous congestion.

b. The pericardial bruits. These bruits do not come from within the heart itself, but are extra-cardial. They consist in frictional noises due to the pericardium having become so altered that its surface is no longer smooth and slippery, but rough and dry. The bruits are characterized by being scratching, grating or creaking, frictional tones not intimately related to either systole or diastole. Pericardial noises when present, prevent the regular heart sounds from being heard.

A pericardial metallic gurgling or liquid bruit, synchronous with the heart's beat, occurs in the course of traumatic pericarditis when fluid exudate and gas commingle in the pericardium.

Diseases of the Circulatory Apparatus.

Acute myocarditis. A diffuse parenchymatous affection of the heart's muscle which attends severe infectious diseases. Symptoms: great weakness and debility, mucous membranes cyanotic, high fever, heart's beat weak, systolic sound muffled. Pulse very rapid up to 120 in the horse; small, weak, arhythmic, unequal, finally imperceptible. Course acute or peracute. Mortality high.

Hypertrophy and dilatation of the heart. Can be present for years without visible symptoms occurring. Symptoms: Pulse strong, also heart impulse, zone of cardiac dullness enlarged on percussion. Later when the heart is greatly dilated and the valves can no longer close sufficiently, symptoms of bicuspid insufficiency occur: pulse rapid, arhythmic, uneven; heart's beat sometimes palpitating, increased dullness on percussion.
Systolic blowing bruit, diastolic sound intact or louder than normal. Exercise causes dyspnoea from pulmonary venous congestion. Termination as in chronic valvular disease. Most common heart disease of horse and dog.

**Acute Endocarditis.** Not very common. Fever, greatly accelerated heart’s action, irregular pulse, intermittent, very small. Heart sounds are at first normal, later systolic bruit. Dyspnoea. General condition altered. Prognosis unfavorable.

**Valvular disease, chronic endocarditis.** Caused by a chronic valvular endocarditis which leads to an atrophy of the valves (insufficiency) or to a narrowing of the orifices (stenosis). Following valvular failure a hypertrophy of the ventricle always takes place; in disease of the semi-lunar valves the left ventricle, in defect of the mitral valve a hypertrophy of the right ventricle. The hypertrophy of the ventricle, which is combined with dilatation, is compensatory.

**Bicuspid insufficiency.** Most common form of heart disease in dogs and horses. Pulse small, irregular. Systolic bruit. Diastolic sound clear, loud. Dyspnoea on exercise.

**Stenosis of the bicuspid valves.** Rare when unattended with insufficiency; an uncommon lesion compared with insufficiency. Pulse small and very weak. Diastolic and pre-systolic bruits. Great dyspnoea.

**Insufficiency of the tricuspid valves.** Rarely primary in the horse, mostly secondary to diseases involving the left ventricle, leading to hypertrophy of the right heart. In the ox frequently primary. Systolic bruits, venous congestion, venous pulse.

**Stenosis of the tricuspid valves.** Happens only in the ox and is then combined with insufficiency. Diastolic bruits, great venous congestion, dyspnoea.

**Insufficiency of the aortal-lunar valves.** Full, strong, hopping pulse, pulsation in peripheral arteries. Diastolic bruit. Hypertrophy of the left heart.

**Stenosis of the aorta.** Mostly combined with insufficiency. Harsh systolic bruit. Long-drawn-out, slow, small pulse (28-32 in the horse). Hypertrophy, attacks of vertigo during exercise (work).

**Valvular diseases of the pulmonary artery** are very rare.

**Termination of all valvular diseases.** In chronic heart diseases the dilatation of the ventricle is followed by a relative insufficiency of the valves. Semi-lunar defects lead to a relative insufficiency of bicuspid; bicuspid defects to a relative insufficiency of the tricuspid. The special diagnosis of the primary lesion is then very difficult. As sequela, finally, the following symptoms appear: small, irregular pulse, systolic and diastolic bruits, congestion of veins, venous pulse, oedemas, dyspnoea, albuminuria, dropsy, attacks of vertigo, emaciation and great weakness.

**Pericarditis.** Mostly a symptom of other diseases. Moderate fever, congestion of mucous membranes. Pulse rapid, heart's beat weak or imperceptible, zone of cardiac dullness increased, pericardial (frictional) bruits, which disappear when fluid exudate becomes prevalent. The pressure of the exudate upon the veins causes congestion in jugulars (venous pulse).

**Traumatic pericarditis of the ox.** Begins usually with the symptoms of
an acute indigestion (traumatic inflammation of the stomach and diaphragm), which may continue for some time. If the pointed foreign body is driven forward, which is commonly caused by the expulsive efforts of the abdominal muscles during the act of parturition, it usually reaches the heart. The general condition of the patient is greatly disturbed, the expression complaining, anxious. The animals stand with back arched and held stiffly, do not like to lie down, and when recumbent rest continually on the sternum. When arising they utter complaints. Temperature variable, external (surface) temperature never quite normal. Pulse rapid, artery tense. Heart beat cannot be felt, zone of cardiac dullness increased and tympanitic when gas has accumulated in the pericardium. On auscultation in the earlier stages pericardial frictional bruits, heart sounds clear, when much exudate is present weak; systolic bruits of a metallic character in consequence of spasm-like contractions of the heart. When putrefactive gases are present the heart sounds can be so loud and metallic as to be heard at a distance. Jugulars distended, pulsating (undulating), oedema of brisket, neck and throat. Course chronic notwithstanding severity of the ailment. Prognosis bad.

7. Respiratory Apparatus.

The examination of the respiratory tract is one of the most important responsibilities of the veterinarian, first because it is frequently subject to disease, and secondly from its availability to thorough inspection.

From the complex anatomy of the apparatus, and the value to diagnostics of the varied clinical phenomena it manifests in disease, a searching examination of the respiratory tract can only be made by following a definite system.

The examination would include attention to the following:

I. the respiratory movements (respirations);
II. the exhaled air (expirium);
III. the nasal discharge;
IV. the nasal mucous membrane and the nasal cavities;
V. the frontal and superior maxillary sinuses;
VI. the intermaxillary space;
VII. the cough;
VIII. the laryngeal region;
IX. the trachea;
X. the percussion of the thorax;
XI. the auscultation of the thorax;

I. The respiratory movements. The respiration should be examined in regard to frequency, manner in which produced, and any special sounds originating during the act of breathing. These three factors help to determine whether dyspnoea be present or not.

Frequency of respirations. To determine the number of respiratory movements per minute each rise or fall of the flanks or ribs is counted. Observing the play of the nostrils is not as certain a method, as these organs can be voluntarily moved by the animal. In winter the breath can be seen appearing as steam at each expiration. The respirations should be counted for at least thirty seconds; in restless animals the veterinarian should stand quietly near, count several times and take the average obtained as the respiratory frequency.

The smaller the animal the greater the number of respirations. In one and the same animal the number of respirations per minute will vary within physiological limits.

Just after partaking of food, or when the abdomen is very full, and especially after exercise, an acceleration of respirations is a normal consequence. High atmospheric temperatures also make the breathing more hurried. In adult animals standing at perfect rest the following number of respiratory movements per minute may be taken as the average normal:

<table>
<thead>
<tr>
<th>Animal</th>
<th>Minimum</th>
<th>Maximum</th>
</tr>
</thead>
<tbody>
<tr>
<td>horse</td>

</tbody>
</table>

A pathological increase in the number of respiratory movements is spoken of as dyspnoea (see this). A decrease in the number of respiratory movements is rarely observed. It is seen in severe brain affections (hemorrhage, hydrocephalus, tumors, poisonings, action of septic substances during the
course of pulmonary gangrene), also where the anterior air passages are occluded (stenosis), which is combined with a pronounced inspiratory tone.

Physiology of respiration. When an animal is at perfect rest, the respirations are produced by the action of the diaphragm. The contraction of the diaphragm produces a dilatation of the thorax. When the organ contracts it flattens and is drawn backwardly, the false ribs becoming elevated. Notwithstanding that the diaphragm is stretched transversely between the thoracic and abdominal cavities, its contraction does not cause its points of insertion to approach each other, for the reason that the intestines keep it continually forward, which produces a drawing anteriorly of the ribs rather than to cause them to approach the median line. On account of the double articulation of the ribs with the dorsal vertebrae the forward movement of them is accompanied by a rotation. The diaphragm dilates the thorax in that it draws the ribs forward and rotates them outward at the same time.

The expiration follows the relaxation of the diaphragm, which takes place immediately after the inspiration. The duration of expiration is longer than that of inspiration; between them in quietly breathing animals there is a short pause.

The normal rhythm of the respirations can be pathologically altered in that:

a. the inspiratory movement lasts too long, the free entrance of air being prevented by stenosis of the respiratory passages.

b. the expiratory act lasts too long, the relaxation of the diaphragm not sufficing to a complete expiratory movement because the lungs have lost their power of contraction (emphysema).

As the respirations are in a measure controllable by the will, which depends upon the cerebrum, excitement or inflammatory conditions occasioning either brain irritation or depression, at times can bring about marked change in the rhythm of respiration. The value of these changes to diagnostics is limited.

The intensity (depth) of the respirations is not marked in healthy animals standing at rest. The alae of the nostrils are hardly moved, and the ribs but slightly raised. The intensity is increased by exercise; if it
is augmented and the animal at rest, it denotes disease. Horses dilate the nostrils trumpet-like, dogs open the mouth (pant) and protrude the tongue. The movements of the ribs and flanks are pronounced. The development of the intensity agrees with the degree of dyspnoea.

The intensity is diminished when the pleura, chest wall or diaphragm is diseased.

The intensity can become asymmetrical in that one side of the thorax undergoes a deeper or more rapid movement than the other side. Asymmetrical depth of respirations is seen in unilateral pneumonias or pleurites.

When the rhythm and intensity of breathing is normal the ribs and abdomen are moved with even regularity, and the type of the respirations are spoken of as costo-abdominal. If the respiratory movements are produced principally by the auxiliary muscles of breathing, which dilate the thorax, the type becomes costal. The costal type is seen to occur where air can not pass freely into the thorax or where the diaphragm or adjacent organs are diseased. (Abdominal tumors, ascites, tympanitis).

When the abdominal muscles are more active in producing the respiratory movement than the thoracic muscles the type of breathing becomes abdominal. The abdominal type prevails when painful conditions of the chest wall are present and where expiration is difficult, as in pulmonary emphysema (heaves).

Respiratory Sounds.

The respirations of healthy animals are performed noiselessly. Only occasionally do they voluntarily emit audible sounds during the act of breathing.

Normal noises occurring during breathing. Very fat cattle which have just finished a feed and have lain down, sometimes groan and grunt as if they were sick. When excited suddenly by
perceiving peculiar looking objects, strange persons, unaccustomed odors etc., horses and cattle *snort* by violently and noisily forcing air through the dilated nostrils. Horses of lively temperament usually snort when led at the end of the halter. Horses blow their noses by causing a forced expiration which is accompanied by a vacillating noise. As in man, dust or mucus is thus removed from the nasal organs. Fat, rough coated dogs *pant* when the weather is warm even when they are at rest. While performing hard work or during forced exercise the breathing is rapid and deep; the air passing in and out of the dilated nostrils at each in- and expiration produces a perceptible *puffing* sound. Spirited horses while being ridden at a gallop, emit a blowing expiratory sound every time the forefeet come in contact with the ground.

A *yawn* is a long-drawn-out, deep inspiration taken with the mouth held wide open. The inspiratory muscles assist in producing it.

**Pathological noises occurring during breathing.** When the respiratory apparatus is diseased the following *pathological sounds* may occur:

1. The *wheezing* or *blowing* sound which is stenotic in its character, emanates from the nasal cavities. It is more pronounced at inspiration, and results from a narrowing of the nasal chambers due to the presence of tumors, swelling of the alae of the nostrils, septum or choanae, enlargements of the turbinated bones or fractures of these bones, fractures of the nasal bones, or deposits of exudate on the mucous membrane. Depending upon the condition of the mucous membrane the stenotic sound may be accompanied by either moist or dry rattling noises.

2. *Snoring* takes place when the act of breathing is effected through the open mouth, the soft palate undergoing a fluttering motion. In swine and dogs it occurs when the lumen or the nasal cavities is contracted by swelling or thickening of the mucous membrane. Snoring is also noted in the ox when the retro-pharyngeal lymph glands are swollen or
enlarged; further in the course of parturient paresis. Horses under chloroform sometimes snore.

3. *Rattling* is a stenotic laryngeal sound which occurs when the vocal cords are relaxed. It is heard in severe inflammations of the larynx or of the neighboring pharyngeal mucous membrane; phlegmona of the pharynx and cedema of the glottis.

4. "The Mucous Click" (klatschender Nasallton) is a peculiar metallic, short expiratory sound first described by Dieckenhoff. It occurs during an inspiratory-expiratory dyspnoea if the nasal mucous membrane is very moist. At a forced inspiration that part of the nasal mucous membrane which unites with the skin of the false nostril, is sucked against the opposite wall to which it adheres for a moment; when an expiration takes place this adhesion is broken, causing a metallic "slapping" tone to be emitted. This sound is of no significance.

5. The most important pathological respiratory tone is the stenotic laryngeal tone. Normally the sound emitted by the larynx is a soft stenotic sound audible when the ear is placed over the organ. [It can be imitated by pronouncing the German "ch"][1]. If the lumen of the larynx is contracted, the noise becomes loud. It is most frequently heard in the horse, and is one of the characteristic symptoms of roaring. The tone is emitted when the inspiration is forced [after exercise] and as to character will vary from whistling to a pronounced hoarse or roaring tone.

Besides it may be due to a firm swelling of the laryngeal mucous membrane (phlegmonous laryngitis, strangles), tumors in the larynx or its neighborhood which prevent the free entrance of air.

6. *Loud rattling noises* [garglings] are heard when the larynx or the trachea contains loose masses of mucus.

7. *Sneezing* is an explosive expiration through the nose, which originates reflexly from irritations to the nasal mucous membrane. It is heard in rhinitis (nasal catarrh) or when for-
eign bodies enter the nasal cavities. Sneezing only occurs in the dog, cat, and fowl.

8. Groaning is heard when a long deep inspiration is followed by an expiration through the partially closed glottis. The sound is only audible at expiration. It is noted in all painful conditions, especially of the thorax.

**Labored Breathing, Dyspnoea.**

The collective term dyspnoea is applied to essential deviations from the normal in the frequency and kind of respiratory movements, and the occurrence of accompanying pathological sounds. Clinically the presence of dyspnoea is recognized:

1. if the respirations are accelerated (altered in number), and the increased frequency is not attended with change in the method of breathing, *simple dyspnoea*.

2. if the respirations are labored (altered in quality), though the frequency may be normal, *aggravated dyspnoea*. The occurrence of respiratory noises always indicates a difficulty in breathing. Depending upon whether the expiration or inspiration is difficult, an *expiratory* or *inspiratory* dyspnoea is distinguished.

If the breathing is hurried and at the same time labored, the *dyspnoea is mixed*.

Depending upon the seat of the obstruction to free respirations, *nasal, laryngeal, tracheal* or *pulmonary* dyspnoea may be present.

Physiologically a dyspnoea occurs whenever the blood flowing through the respiratory center contains an abnormal amount of CO₂. Accordingly, anything which increases the quantity of CO₂ in the tissues, or interferes with the exchange of gases in the lungs, can cause a dyspnoea.

*Simple dyspnoea* is characterized by the number of respirations being increased without the quality of the respira-
tions suffering change. In the horse for instance, the number of respirations can exceed 120 per minute and be superficial, only the nostrils becoming dilated. If, however, the respirations are very difficult, it ceases to be simple dyspnoea, for the method of breathing becomes more intensive and labored, and the dyspnoea mixed.

Simple dyspnoea appears:
1. in fever; the degree of respiratory frequency depends upon the severity and nature of the disease.
2. in all conditions which make the respiratory act painful: diseases of the pleura, diaphragm, thoracic wall, peritoneum.
3. where the breathing surface of the lung is decreased or where the organ is prevented from properly expanding: pneumonia, pulmonary tuberculosis, abdominal tympanitis, ascites.

In diseases of the heart which have a congestion of the blood in the lungs as a consequence.

The inspiratory dyspnoea. If the entrance of air into the respiratory organs is made difficult, the animal seeks to overcome the condition by taking forced inspirations. Not only is the diaphragm actively employed, but other muscles which are normally not used during inspiration are called into play. These muscles are: the serratus anticus major; serratus posterior, external intercostals, levators costarum, ilio costalis, scalenus. The following clinical symptoms characterize dyspnoea:

The nostrils are widely distended; dogs, fowls, cattle and swine breathe with their mouths open. Dogs sometimes close the jaws and breathe through the lateral commissures of the mouth, sucking in the cheek at each inspiration. The head and neck are extended horizontally, the larynx is retracted, the ribs greatly elevated and rolled forward. The forelimbs are spread far apart and the elbows turned out so that the serrati and pectoral muscles can better come into play.

If, in aggravated inspiratory dyspnoea, the air enters the lung very slowly, notwithstanding that the ribs are greatly
elevated, and the thorax is distended to a degree which does not correspond to the quantity of air passing in, a suction pressure will occur, which can be recognized by a *sinking of the lower anterior thoracic wall*—particularly of its intercostal spaces.

**Inspiratory dyspnoea is observed:**

1. in a pure form in bilateral paralysis (paraplegia) of the larynx and in severe cases of unilateral paralysis of the organ (hemiplegia, roaring). It is characterized by the above cited inspiratory dyspnoea and the appearance of a stenotic laryngeal bruit. In less severe cases of roaring this symptom can only be brought out by exercising the patient. The act of expiration is performed without difficulty.

2. in less pure form where a stenosis of the nasal passages, pharynx, larynx or trachea exists; the result of inflammatory swellings, tumors etc.

3. in diseases of the bronchi and pulmonary tissues preventing the free entrance of air into the lung: bronchitis, pulmonary oedema, pneumonia.

4. where the principal respiratory muscle, the diaphragm, is inactive: rupture of inflammation, tympanitis.

**Expiratory dyspnoea.** This occurs when the exit of the air from the lung is made difficult. In this case the expiration ensues not alone passively, but the accessory expiratory muscles actively interfere. The muscles aiding expiration are: the abdominal muscles (external and internal oblique, straight abdominal muscle), the internal intercostals and triangularis. An expiratory dyspnoea is recognized by the following symptoms: The expiration is prolonged and is attended with pronounced movement of the abdominal walls (*pumping of the flanks*). At first, a limited sinking of the thoracic walls ensues from a relaxation of the diaphragm, then the abdominal muscles become active (contract) and a furrow is formed along the course of their insertion to the costal cartilages—the so called "*heave line*." The passive and active moments of expiration can be plainly distinguished from each other, so that
the movement of the flank appears to be a double pumping. The back is elevated at expiration and sinks during inspiration. At the moment of expiration the anus is greatly protruded in expiratory dyspnoea. When the abdomen is well filled, these symptoms appear more prominently.

Expiratory dyspnoea occurs:
1. in vesicular and interstitial emphysema.
2. in chronic bronchitis and peri-bronchitis.
3. where the lung has adhered to the costal wall.

A mixed dyspnoea is present when accelerated respiratory frequency is combined with difficult inspiration and expiration (inspiratory and expiratory dyspnoea). It is the most common form of dyspnoea and attends all severe diseases of the respiratory tract (pneumothorax, hydrothorax) and also those diseases which have no primary seat but whose course is accompanied by a severe intoxication of the blood with CO2—as in many of the infectious diseases.

II. The exhalations (expirium). An examination of the air breathed out by the lungs is of diagnostic importance in many morbid conditions. Normally the air is emitted from the nostrils in two odorless currents of equal size. The two deviations from the normal are:

1) the air currents from both nostrils are not of equal size. Where one of the currents is smaller (of less volume) than the other, it points to a narrowing of the nasal passage of that side. Not infrequently a blowing sound accompanies the inspiration. The passage may be constricted by thickenings or swellings of the mucous membrane or by tumors.

2) the expirium has a bad odor. A bad odor from the nostrils is always a sign that putrid decomposition is taking place in the air passages. The odor may emanate from different parts of the respiratory tract. The odor is either putrid (fetid) or carious. It is observed:

in stagnant masses of putrefying exudate in the nasal
conchæ, sinuses, guttural pouches, or even on the mucous membrane of the upper air passages and bronchi.

in putrid decomposition of tumors in the air passages.

in suppuration or necrosis of the bones of the head bordering on the air passages: Suppuration in the tooth alveoli, dental caries, necrosis of the turbinated bones.

in gangrene of the lungs.

It is always important to determine where the odor originates. At first we should be clear as to whether it really comes from the nose or from the mouth. When the mouth is closed, this is usually not difficult; in doubtful cases the odor of the saliva can be tested. The safest way is to make an examination of the buccal cavity, especially of the teeth. When the alveoli of the upper molars are diseased, a carious smell is emitted from both the mouth and nose. (See Examination of the Mouth).

If the offensive odor has been found to come from the expired air, it is then necessary to locate the part of the respiratory apparatus at which the decomposition is taking place. For this purpose we should first determine whether or not the odor is equally offensive from both nostrils. When the odor from one nostril is more prevalent than from the other, the process of decomposition has its seat in the nasal cavity of that side, and usually it is accompanied by a unilateral nasal discharge, bulging of the facial bones and swelling of the submaxillary lymph glands.

The examination of the upper molar teeth of that side should never be neglected.

When the odor is equally offensive from either nostril, the putrid focus is as a rule contained in the lung, more rarely in the pharynx, larynx or trachea.

Putrid decomposition in the lung is not always to be ascribed to pulmonary gangrene, for not infrequently a decomposition of exudate in the bronchi, (fetid bronchitis) is present.
III. Nasal discharge. Only in the ox a slight nasal discharge is seen to occur in health, which the animal usually removes from the nostrils with its tongue. In the other animals the appearance of a nasal discharge is always a sign of disease, and one of considerable diagnostic importance. It can accompany all diseases of the respiratory tract which are exudative in character, such as catarrhs of the nasal cavities, sinuses of the head, throat, larynx, trachea, bronchi and lungs. In these cases the discharge is the product of the disease. Sometimes the discharge comes from the digestive tract, from the mouth or pharynx, more rarely from the gullet or stomach, when it contains substances such as food particles, water or saliva.

The character of the nasal discharge depends upon the organ from which it comes and the nature of the disease producing it. We should bear in mind that the ox, sheep, goat and dog usually lick off the discharge, hence it is not so noticeable in these animals as in the horse.

To correctly judge nasal discharge the following should be considered:

The quantity, which will vary greatly. The discharge is slight in catarrhs that are neither very diffuse nor severe. In tuberculosis, notwithstanding the severity of the case, there is little discharge because what little exudate appears upon the surface of the mucous membranes is removed by coughing and eventually swallowed.

The discharge is copious in strangles and in diffuse catarrhs of the upper air passages and bronchi.

Unilateral nasal discharge is characteristic of disease of one side of the anterior air passages as far back as the fauces. A catarrh involving but one side of the soft palate or pharynx may also show a discharge from only one nostril.

Of especial importance is the variation in quantity of the discharge. In some cases a copious amount of discharge is ejected when the head is suddenly lowered [unreining after a drive], while for a day or more there is present either no dis-
charge at all or only a very slight one. This symptom is characteristic of catarrhs of the frontal and superior-maxillary sinuses and of the guttural pouches.

The color. The color of the nasal discharge depends upon the character of the inflammation, and also the presence of foreign mixtures. It will vary from colorless to grey, white, yellow, red, brown or green in all their different tints. During the course of a disease the color of the nasal discharge will change with the character of the inflammation. A serous or mucous discharge is usually colorless; a purulent discharge is gray or yellow or maybe of a greenish hue.

A green discharge usually is due to an admixture of the chlorophyll of the food, deglutition being difficult. Food particles are always present in such cases. In rare instances a greenish tinge is seen, due to decomposed blood coloring matter being present in the discharge.

A yellow, rust-colored discharge is seen in hemorrhagic hepatization of the lungs (contagious pleuro-pneumonia of the horse). It is due to an admixture of blood coloring matter.

A bloody discharge is observed only when blood in toto is present. It may be due to:

- Finger-nail injuries to the mucous membrane of the nose or fractures of nasal bones. In the dog the presence of Pentastomum tænioides may lead to bloody nasal discharge, and in sheep the larvae of oestrus ovis.
- In glanders; bleeding tumors in the nasal cavities.
- Nasal hemorrhages may attend anthrax, purpura hemorrhagica, or very severe cases of contagious pleuro-pneumonia of the horse.

The consistency of the nasal discharge depends upon what it contains. It may be serous, mucoid or mucilaginous, with varied intermediations. It may also be flocculent, clumpy, or contain great masses of adhering exudate. In the beginning of a catarrh the discharge is serous (clear), but by admixtures of mucus it becomes mucoid, and loses its transparency from the quality of epithelial cells it contains. Its
color is then gray. When an admixture of pus is present the
discharge assumes more of a *cream-like* consistency and its
color changes to gray-yellow or yellow. A discharge of pure
pus only occurs when an abscess ruptures into the nasal cavity.

A *clumpy, buttermilk-like discharge* is observed in chronic catarrh of the sinuses of the head because
the exudate has been retained for a time.

*Adhering masses of exudate* are seen in diphtheritic, croupous, or fibrinous inflammations.

**The odor.** The odor of the nasal discharge becomes *foul, putrid* or *carious* from decomposing processes. In such cases the *expirium* is also tainted. For the determination of the seat of the order, what has been said concerning the odor of the expired air applies.

*Foreign admixtures.* Most commonly we observe *air bubbles* of large or small size which cause the discharge to appear as foam.

*Fine foam.* When the discharge comes from the smaller bronchi in pulmonary edema and bronchitis, the foam is composed of small air bubbles of equal size. When there is much foam the discharge is white in color. Horses suffering from chronic bronchial catarrh after exercise show a white nasal discharge partially made up of fine foam.

*Coarse foam.* This is not infrequently unilateral and contains an admixture of *food particles.* It comes from the mouth and consists in part of saliva. Coarse foam is symptomatic of paralysis of the pharynx, pharyngitis or fungus poisoning.

When *food particles* alone make up the nasal discharge, it is a sign that vomiting has taken place. The discharge is then not foamy, is of acid reaction and contains no admixtures of exudate.

*A microscopical examination* of the nasal discharge is rarely of practical value. It may sometimes be of use to determine the presence of the embryo or egg of Strongylus filaria in the lungs of sheep or of Pentastomum taenioides in the nasal passages of the dog.
The examination for pathogenic microorganisms yields positive results only in exceptional cases. The tubercle bacilli are one of these exceptions as their characteristic way of excepting stains serves to identify them microscopically.

Fig. 23.

Tubercle bacilli.

Microscopical determination of tubercle bacilli. A cover-glass preparation is covered with Ziehl's carbolized-fuchsin solution (fuchsin 1, absolute alcohol 10, carabolic acid 5, aq. dest. 95), and heated repeatedly for about two minutes over a flame. Wash and drain. Gabbit's solution (methyl blue 2, in 100 grammes of a 25% sulphuric acid) is then applied and allowed to remain ½ minute. Wash and examine.

IV. The examination of the nose and upper air passages. The external appearance of the facial bones will readily betray any deformity. Circumscribed enlargements are due to tumors and a bulging of the sinuses in chronic catarrhs. Diffuse enlargements attend rachitis and osteoporosis, "big head" Depressions have a traumatic origin. swellings appearing at the nasal openings and nostrils are common in purpura hemorrhagica. Tumors (atheromas) are frequent in the false nostril.

The specific pathological conditions which occur about the lips and nose are the pustules and ulcers which attend contagious stomatitis, the pox pustules of sheep pox, and the vesicles on the muzzle of the ox and snout of swine suffering from foot and mouth disease.
When a nasal discharge has existed for a long time, the integument of the nose and lips over which it flows loses its pigment. The white streaks thus formed speak for the chronicity of the discharge.

The examination of the nasal mucous membrane. The nasal mucous membrane is available to inspection only in the horse. Local lesions occurring on it are often of great diagnostic importance.

Method of examination. The head of the animal should be elevated and the inner cartilaginous wing of the nostril grasped between the thumb and middle finger which draws it upward and outward; the extended index finger is then inserted under the outer wing, which it distends. The patient should face the light, except when the rhinoscope (an enlarged opthalmoscope) is used.

Fig. 24.

Examination of the Nasal Mucous Membrane.

Discolorations. Indistinct, punctiform, or ramiform redness is not infrequently seen in acute and chronic catarrhs; they are due to the peculiar anastomosing of the capillaries and are of no diagnostic value.

Deep redness is mostly the result of hemorrhages in the mucous membrane. They appear mostly punctiform and can be as large as a ten cent piece, they are well circumscribed and of round form (petechiae, ecchymoses). When they become
confluent, the redness is diffuse or appears in irregular streaks. Petechiae are most commonly seen in purpura hemorrhagica, but may also occur in anæmia and in leucæmia. The spots, which are at first dark red, soon fade and assume a brownish hue. Such suffusions are also observed in septicæmic diseases: anthrax, septicæmia.

Swelling of the nasal mucous membrane is characterized by the normal surface of the mucous membrane, which is granular from the many glands it contains, becoming firm and smooth. As the membrane is usually tense, the swelling is not marked. Its origin is inflammation, therefore the surface appears turbid.

Chronic, connective tissue thickenings are most commonly made manifest by irregular, wart-like prominences which show the characteristics of scars.

Wounds in the mucous membrane are very often caused by finger-nails, sharp straws and the like.

Nodules from the size of a millet seed to that of a peppercorn almost exclusively attend glanders. Exceptionally they result from contagious stomatitis, but in such cases like nodules are to be found in the mucous membrane of the mouth. Isolated nodules are seen in follicular catarrh, a very rare disease. To prevent mistaking particles of mucus for true nodules, the supposed nodule should be palpated with the finger; if mucus particles, we can thus wipe them off.

Next to nodules, ulcers form the most important criterium in diagnosing glanders. Glanders ulcers have jagged borders circumscribed by rounded, elevated walls. The base of the ulcer is sunken, uneven, gray in color, and of lardaceous appearance. The favorite seat of the glanders ulcer is on the medial border of the inner cartilaginous wing of the nostril, hence this place should always be examined.

In rare cases ulceration of the nasal mucous membrane also attends stomatitis and purpura hemorrhagica. For dif-
ferentiation the concomitant symptoms must be considered, such as ulcers on the buccal mucous membrane, petechiae, etc.

Very superficial pittings with sharp borders—not rounded nor red colored—represent the catarrhal or erosion ulcer.

Cicatrices at the lower end of the nasal septum are mostly the result of previous wounds. They are often curved (as if made with a finger-nail. Glanders cicatrices are as a rule more or less star-shaped.

The examination of the sinuses of the head is often of importance and should be made whenever a chronic nasal discharge exists, especially when attended with an unilateral bulging (enlargement) of the facial bones. Mere enlargements can be defined by palpation. The presence of exudates in the sinuses can sometimes be determined by percussion. The normal percussion sound of the sinuses is full, but when they are filled it becomes empty. When the sinuses are only partially filled the percussion sound is not changed. Negative results from percussion, therefore, do not exclude the presence of exudate.

V. Examination of the submaxillary lymph glands. Although these glands do not properly belong to the respiratory apparatus, the examination of them is significant in the horse. In this animal especially, the glands become sympathetically diseased when pathological conditions exist within the domain of their lymph vessels.

Anatomy. The lymph vessels from the nostrils to the ethmoid bone carry their lymph to the sub-maxillary glands, a small glandular packet as broad as and a little longer than a finger, lying on each side of the intermaxillary space. They begin at the point where the inferior maxillary artery passes under the ramus of the lower jaw, and extend forward to the angle of the chin where each unites with its fellow of the opposite side. Each lobule is of about the size of a small bean. In horses of coarse conformation the intermaxillary space is often filled without the glands being swollen.

As soon as an absorption of irritant or infectious substances [bacteria] takes place in the region drained by the lymph vessels of the sub-maxillary glands, these
organs become secondarily diseased. The primary disease usually has its seat in the mucous membrane of the nasal passages or sinuses. An examination of the glands, therefore, is of great significance in determining the pathological condition of these mucous membranes.

In making the examination the following points are to be considered:

Is one or both glands enlarged? In acute infectious catarrh the glandular swelling is generally bilateral; inlanders frequently unilateral, and in tumors in the nasal passages, bad teeth and chronic catarrh of the sinuses, it is, as a rule, unilateral.

Size and form of the glandular swelling. Many or a few of the lobules may be enlarged to the size of a bean, pigeon or hen's egg, depending upon the primary disease in the mucous membranes. Acute swellings are smooth; chronic swellings lobulated (nodular), which is especially marked in inlanders.

Consistency of the swollen glands. The swelling is soft in serous, tense and firm in cellular infiltration of the glands. Acute diffuse swellings (strangles) leads often to suppuration (abscess), which can be determined by fluctuation. In inlanders diffuse abscess formation never occurs in the glands; only rarely does a small purulent focus (farcy bud) appear in the skin over the gland. Firm, hard enlargements are always due to some chronic irritation and consist of connective tissue proliferations. Such attend chronic inlanders, catarrhs and dental fistulae. Extensive well defined enlargements of the individual glandular lobules are observed in leucæmia and when malignant tumors are present.

Temperature and sensitiveness. When the glands are hot and tender (inflamed), the morbid condition is acute (strangles). If the enlargement of the gland is firm, cold and painless, it points to inlanders, chronic catarrh, tumors or hyperplasias [leucæmia].
Movability of the glands. If the irritation is chronic and attended with the formation of new connective tissue, the process involves the environing tissue, forming adhesions with its neighborhood. In acute purulent inflammation of the glands there develops in the vicinity, namely, directly beneath the skin, an inflammatory edematous or, perhaps, a phlegmonous swelling.

The extirpation of a diseased lymph gland is recommended where glanders is suspected. Its object is the patho-anatomical or bacteriological examination of the gland. The operation can be performed on the standing animal when local anesthesia is employed, and is not dangerous.

VI. Cough. Cough is a suddenly occurring expiratory impulse which follows a deep inspiration. The glottis is forcibly opened during the act, causing a sound to be emitted. By coughing accumulations of mucus are removed from the bronchi, trachea or larynx. In animals cough is a reflex action which can to a certain extent be suppressed. Although it can be induced by irritation to many peripheral nerves, as a rule it emanates from branches of the vagus nerve in the respiratory apparatus. Most sensitive in this particular is the superior laryngeal nerve of the larynx and the first three rings of the trachea. The mucous membrane of the trachea is less sensitive, except at the bifurcation of the bronchi. The bronchi are just as easily irritated as the larynx; but cough cannot be excited from the parenchyma of the lungs. It can, however, emanate from the pleura when this organ is in a state of irritation. Peripheral irritation is transmitted to the cough-center in the brain, which innervates the expiratory muscles and recurrent nerve, inducing the reflex spasm called cough.

In exceptional cases cough can emanate from terminals of the vagus nerve lying outside of the respiratory apparatus, as, for instance, from the external auditory meatus [ear], nose, or abdominal organs. According to Albrecht cough can occur from abscess in the liver. These are, however, exceptional cases. Cough from the stomach has never been observed in the horse. There is a possibility that cough may have its origin in the brain. These exceptions are worthy
of note and should be considered in those cases of cough the cause of which can not be determined to lie in the respiratory apparatus.

**Cough occurs:**

- If foreign bodies are inhaled: smoke, dust (dusty food), acrid gases (ammonia, sulphurous acid, chlorine etc.)

- If cold air is inhaled, especially if the respiratory tract is inflamed: catarrhs of the respiratory mucous membrane, pleuritis, traumatic injuries to the pleura (traumatic gastro-diaphragmitis of the ox)

- If mucus, exudate or foreign bodies (food) and parasites are present in the air passages: Gastrus lavae in the larynx, Syngamus trachealis in the wind pipe, Strongyli in the bronchi.

In no case can cough originate when the sensory terminals of the vagus nerve are no longer susceptible to irritation. In severe phlegmonous diseases of the mucous membrane, cough is absent. The cough center in the brain must also be in normal condition. It is disturbed when great mental depression exists. Therefore, when appreciable irritations (rales) are present, unaccompanied by cough, the prognosis is an unfavorable one.

**The character of the cough.** The character of the cough varies with the species of animal. Healthy horses have a strong, vigorous, loud, full-toned cough; cattle a sharper defined, softer toneless, prolonged cough, the glottis being held open. The appearance of cough in animals is always abnormal; its character depends upon the disease which causes it. Whether cough accompanies the disease or not can usually be learned from the anamnesis, although we can not depend upon this to determine its character. It is always best that we induce the patient to cough in our presence; this may be done by pressing the hand against the upper three rings of the trachea or the finger ends against the arytenoid cartilages of the larynx. In sensitive healthy horses one or a few short coughs will follow the manipulation, while in indolent individuals there is no
reaction. In the ox coughing can only be induced in this way when the animal is diseased.

If the ox can be made to cough by pressing the upper trachea or larynx, or if coughing takes place in the horse when only slight pressure has been used, some abnormal irritation exists. If cough can be readily induced by pressing the lower windpipe, a tracheitis is present.

When cough exists the following should be considered concerning its character:

The frequency of the cough. A cough may be **occasional** or **frequent, continual** or **transitory**. If the cough is occasional usually only one or a few impulses occur, but when frequent several in succession—a fit of coughing.

The painfulness of the cough is cognized by the general behavior of the patient which seeks to suppress the pain by shaking the head and making masticatory and swallowing movements. The animal may also be restless, paw and groan. A painful, **painless, burdensome, and torturing** cough may be distinguished. The cough is painful in acute bronchitis, pleurisy, pleurodynia, and in so called “whooping cough” of dogs; painless in chronic laryngitis.

The force of the cough impulse depends upon the vigor of action of the respiratory muscles. Accordingly, the cough may be **strong, vigorous, or weak**. It is weak if expiration is difficult or if the patient is unable to cough vigorously: reduced, debilitated animals, pulmonary emphysema, bronchitis, hydrothorax; or if the expiration is painful: pleurisy, pneumonia, pleurodynia. The cough is strong if the elasticity of the lungs is normal and no pain attends the act.

The duration of the cough impulse is determined by the force with which the pulmonary air is held repressed by the closed glottis. If the pressure is great, the glottis will be suddenly forced open and the cough will be short. If the glottis is not completely closed (paralysis of the arytenoid cartilage—roaring) or the repression of the air causes pain (pleurisy), the cough is long—**prolonged**.
The depth and magnitude of the cough depend partly upon the force and duration of the cough impulse. The magnitude is influenced by the quantity of expelled air. We speak of a deep and a shallow cough.

The cough sound is dependent upon the force of the cough impulse, the tension of the vocal cords and the special condition of the surface of the mucous membrane. The sound may be loud—low, clear, dull; sharp, whistling, dense—hollow; loose, moist—dry.

The "return impulse" of the cough (Hustenrueckstoss). Each cough is followed by a short, deep inspiration. If the glottis is not fully open at the moment this inspiration takes place, the air rushing in causes the partially stretched vocal cords to vibrate, causing a harsh, short, laryngeal stenotic sound to be emitted. It is heard in paralysis of the larynx (paraplegia, hemiplegia) and in severe inflammatory swelling.

The act of coughing tends to eject masses of mucus, exudate etc. from the bronchi, trachea, and larynx. Animals do not expectorate because that which is coughed up into the throat, as soon as it reaches the pharynx, is swallowed. Sometimes, however, a part is discharged through the mouth, the lower naso-pharyngeal wall and the soft palate being forced forward by the air passing out, which leaves the opening into the buccal cavity free. The thus expectorated mass is usually mixed with mucus from the pharynx and mouth and also with food particles.

Addendum. Change in voice is of little significance in animals. Commonly we observe a hoarse voice in laryngeal catarrhs. This is most marked in dogs. In rabies the voice suffers change. In dogs affected with this disease the bark is prolonged into a long, dismal howl, the voice being at the same time hoarse. In horses a short, squealing tone is emitted.

VII. Examination of the larynx and trachea. Enlargements in the region of the larynx are as a rule not confined to this organ, but to neighboring tissues as the pharynx, lymph glands, sub-
cutis. When we determine the seat of the enlargements by palpation we may at the same time note their temperature, sensitiveness, and the ease with which cough can be induced by pressing upon them. Where much exudation is found in the larynx, infiltration of the vocal cords or other folds of mucous membrane, a trembling of the organ may be felt (laryngeal fremitus).

On auscultation of the larynx or trachea, normally a stenotic sound is heard [like a German “ch”]. It is due to a vibration of the vocal cords and laryngeal walls which is produced by the air forced through the organ. It is heard best at expiration. When the mucous membrane of the larynx is swollen and firm, this sound becomes very pronounced and assumes a whistling or hissing character. If the swelling of the laryngeal mucous membrane is loose, or deposits of exudate cover the membrane, the sound produced is rattling or purring.

In examining the trachea we should look out for scars resulting from tracheotomy wounds. The form of the trachea should also be noted. In chronic tracheitis of the ox the trachea may be shaped like a saber scabbard.

Laryngoscopical examination. With the aid of the laryngoscope invented by Polansky and Schindelka, the interior of the larynx may be examined directly. For the diagnosis of inflammatory conditions in the larynx this examination is of no practical value. However, in paralysis of the arytenoid cartilages the instrument can be used to advantage. [This instrument, which is a modified endoscope, consists of a cylinder 56 cm long and 4.7 cm in diameter, at one end of which is an optical illuminating apparatus. The light is furnished by an electric battery, and undue heat is prevented by a special cooling arrangement. The instrument is inserted through the nostrils and can be used in the horse without casting.] In left-sided paralysis of the larynx (roaring) the left arytenoid cartilage is seen to project farther into the lumen of the larynx than the right one. This is plainest to be seen when the larynx is moving. As the larynx of the horse is usually held in the position of “middle inspiration,” it is necessary to induce forced inspiration and expiration. To do this the thorax is encircled with a girth which is slowly and gently drawn tight and relaxed, alternately, imitating forced breathing. The larynx in the meantime is watched through the instrument. At each inspiration the healthy cartilage is seen to move outwardly while at each expiration it approaches the middle line. The diseased cartilage, on the other hand, either remains completely at rest (paralysis) or its movements are very tardily performed (paresis).
In bi-lateral paralysis (paraplegia) of the larynx as a rule dyspnœa is shown when the patient is at rest, at least if it is at all excited. In this case both arytenoids can be seen protruding into the lumen of the larynx at each inspiration; at each expiration they are forced flutteringly aside. The paralysis can be complete or incomplete, and is often better developed on one side than on the other.

VIII. Percussion of the Thorax. To properly percuss the lungs a knowledge of their topographical position is essential.

Anatomy. The lungs and heart do not occupy the whole of the thoracic space. The abdominal viscera encroach upon a greater part of it. The partition between the chest and abdominal organs is the diaphragm.

Fig. 25

Heart; — — Line of Insertion of Diaphragm; — Boundary of Lung during Expiration.

This organ is inserted, in the arc of a circle, to the inner surface of the whole thorax, reaching in an oblique direction from the sternum backwards and upwardly to the lumbar vertebrae. In the region of the sternum its points of attachment are at the union of the ribs to their cartilages, farther posteriorly, however, the diaphragm does not extend down as far as the cartilages of the false ribs, but passes obliquely across their inner surfaces until, finally, at the last rib it finds attachment at the superior end. The diaphragm arches forward from its points of insertion,
extending into the thoracic cavity in the shape of a cone the apex of which reaches in the various animals, somewhat beyond the middle of the 7th or 8th rib. At expiration the diaphragm lies with its muscular portion directly against the lateral chest wall, the tendinous portion then forming the partition. With the beginning contraction of the diaphragm at inspiration the arch becomes flattened in that the organ is drawn away from the inner wall of the chest. The space left by the receding diaphragm is immediately occupied by the sharp borders of the lungs which then lie close to the points of insertion of the diaphragm. At the acme of inspiration the rounded, cone-like form of the diaphragm becomes more pointed and its base and apex approach each other, the ribs having been drawn forward. By this drawing forward of the ribs the transverse diameter of the thorax is increased and the base of the cone-like diaphragm broadened. (See page 80).

Accordingly, the lateral border of the lung is continually moving backward and forward, traveling a distance in the larger animals of 1-2 hands breadth, and in the smaller ones from ½ to 1 hands breadth. On an average the posterior border of the lung may be defined by a line which in the larger animals is the width of a hand from the points of insertion of the diaphragm. In small animals the distance is one half this.

Fig. 26

.... Heart; — Boundary of Field of Percussion; — — — Boundary of Lung; — — Insertion of Diaphragm; — — Paunch.

The availability of the lungs for clinical examination. The area of percussion is defined dorsally by the thick muscles of the back. This boundary to percussion, which varies with the condition of the animal, is limited by a line drawn from the
posterior angle of the scapula to the external angle of the ilium. Anteriorly the boundary is formed by the scapula and the massive shoulder muscles.

By drawing the leg forward the field of percussion can be somewhat enlarged. Ventrally the density of the sternum and muscles overlying it renders in this region the lungs unavailable to percussion.

The field of percussion is a right-angled triangle the right angle of which lies at the base of the scapula. In all animals the dorsal and anterior boundaries of the field of percussion are the same, the only variation being in the abdominal boundary.

Horse. The abdominal boundary is a line drawn from the 16th intercostal space, crossing the middle of the thorax at the 11th rib, to the olecranon.

Fig. 27

Heart, shaded part not covered by Lung; Field of Percussion of Lung; — — Insertion of Diaphragm; L Liver; M Spleen; R Rectum; D Small Intestines.

Ox. In ruminants the field of percussion is small on account of the less number of ribs (13) which causes the diaphragm to lie farther forward.
The abdominal boundary in this animal is a line drawn from the 11th intercostal space, crossing the middle of the thorax at the 9th rib, to the olecranon.

Swine. In swine, percussion can rarely be employed, as the thick layer of sub-cutaneous fat and the restlessness of the animal greatly interfere. The abdominal boundary of the field of percussion extends from the 11th rib to the olecranon.

Dog. In the dog the shoulder lies well forward which gives a larger field of percussion. The abdominal boundary of the field extends to the 9th rib at the middle of the chest wall.

The normal pulmonary percussion sound is due to the vibration of the thoracic wall, the elastic pulmonary tissue and to the air contained in the lungs.

The intensity of the sound depends upon the volume of the air containing lung tissue which is set in vibration. It will vary with the force used in percussing, the thickness of the chest wall and the volume of the part of the lung vibrating. Accordingly, more force is employed in percussing a thick walled chest than a thin walled one.

As the normal percussion sound at the boundaries of the field of percussion merges gradually into a tympanitic or a dull sound, the exact borders of the lungs cannot be definitely defined under the hammer.

In vesicular pulmonary emphysema, interstitial emphysema (which is rare), and pneumothorax the field of percussion is somewhat enlarged posteriorly, the diaphragm suffering permanent backward displacement.

An abnormally loud, full sound can be heard under normal conditions if the wall of the chest is very thin, under such circumstances the vibration of the lung being unusually audible.

Exaggerated pulmonary resonance occurs:

1. if the lung is much inflated with air (emphysema).
2. If the lung is abnormally distended with air as it occurs at the border of pleural exudate.

3. In pneumothorax.

If the dull or empty percussion sound is heard where the sound should be resonant, it always signifies disease. It occurs:

1. If the lung tissue becomes dense from a. pneumonic hepatization: in contagious pleuro-pneumonia (Brustseuche) of the horse, and in contagious pleuro-pneumonia of the ox as a rule a large portion of the lung becomes solid and liver-like, and emits. on percussion, a dull or flat sound. In catarrhal pneumonias the pulmonary sound is not so flat, because the solidification of the lung is not complete, the morbid process appearing in the form of more or less isolated centers or foci which are not entirely void of air. In hypostatic, metastatic, and ichorose pneumonias, swine plague, dog distemper, verminous pneumonia and tuberculosis the percussion sound is not diffusely dulled, but a dull sound is emitted over the dense diseased centers only.

b. chronic interstitial pneumonia combined with atelectasis.

2. If tumors or neoformations are present in the lungs: glanders, tuberculosis, carcinoma, sarcoma, echinococci, etc.

3. If an airless, solid medium come between the lung and the pleximeter;

Inflammation, swelling of the thoracic wall (after mustard applications); neoformations on the pleura; collection of considerable pleuritic exudate or transudate in pleuritis, contagious pleuro-pneumonia of the horse, contagious pleuro-pneumonia of the ox, and in swine plague. In the horse the presence of but a few litres of fluid in the chest cannot usually be determined.

Pleuritic dullness is characterized by its horizontal upper boundary which shifts if the position of the body is changed, the contained fluid seeking the lowest level. This latter is most marked in small animals.
The **tympanitic percussion sound** is also abnormal when it occurs in the thorax. It appears:

1) **in collapse of the pulmonary tissue** from a retraction of the lungs in the presence of pleuritic exudate. The collapsed lung floats upon the exudate, hence above the horizontal line of dullness a tympanitic zone exists.

   in the first and last stages (resolution) of pneumonia.

   if numerous, small tumors occur in the lungs and the pulmonary tissue amid them is collapsed.

2) **if caverns, or large bronchiectases** [morbid dilatations of the bronchi] are present in the lungs. The intensity and clearness of the tympanitic tone depends upon whether the cavities momentarily contain air or exudate.

3) **in pneumothorax**.

4) **in prolapsus of bowel** into the thoracic cavity through the ruptured diaphragm.

The tympanitic percussion sound has a **metallic tinkling tone** when the walls of the air-containing cavity are smooth and distended.

**The cracked-pot resonance.** [This resembles the sound produced by striking the hands, loosely folded across each other, against the knee, the contained air being suddenly forced out between the fingers—Loomis]. It occurs in the thorax when a large air-containing cavern is in direct communication with a bronchus. Forcible percussion causes some of the air to be suddenly driven out of the cavern into the communicating bronchus, thus inducing this peculiar resonance. The **cracked-pot resonance, however, does not always indicate the presence of a cavern in the lung.**

**IX. Auscultation of the lungs.** In auscultating the thorax over healthy lung, we perceive a soft, sipping sound, the **vesicular or alveolar murmur.** The sound can be imitated by softly pronouncing the letter "v". It begins with the inspiration, increasing as the inspiration continues, and becomes, at
expiration, a fainter, shorter sound having the character of a softly aspirated letter "f".

The intensity of the murmur depends upon the intensity of the respirations. The more forcible and deeper the respiratory movements, the louder the vesicular murmur. After exercising the animal it is therefore more distinctly audible. As a rule the murmur is softer and less distinct in the horse than in the ox.

Concerning the origin of the vesicular murmur, it is assumed that the sound is simply a continuation of the normal laryngeal stenotic sound which has become modified in the bronchioli. During inspiration the sound producing stream of air is directed toward the ear, therefore the vesicular respiration is more audible at inspiration than at expiration.

As with the laryngeal respiratory sound, so are other sounds originating in the upper air passages transmitted to the lungs. These are rattling throat sounds, wheezing, groaning etc. Their appearance in the chest has no diagnostic significance.

Alterations in the vesicular respiration. An exaggerated vesicular respiration occurs:

if the respirations are intensified, therefore in physiological and pathological dyspnoea.

if it is compensatory; that is, if one portion of the lung is required to perform extra work for another portion which is diseased and incapable of taking part in the respiratory act. [For instance, where one lung does the duty of its fellow which is diseased.]

if a bronchitis is setting in, the lumen of the bronchi being contracted by swelling of, or collections of exudate on, the mucous membrane. The exaggerated vesicular murmur in such cases is a symptom of great diagnostic importance.

A diminished or feeble vesicular respiration occurs:

if the thoracic wall is thickened from fat accumulations or disease: swelling, neoformations.
if the air cannot enter the vesicles in consequence of great swelling or plugging of the bronchi: severe bronchitis.

if the exchange of gases in the lungs is impaired: emphysema, beginning hepatization, and a partial compression of the lungs by pleuritic exudate.

Absence of the vesicular murmur, and no other sounds present in the lung [i.e. total absence of any pulmonary sound] occurs:

if pleural exudates or tumors have displaced the lung tissue:

rarely in severe vesicular pulmonary emphysema, or a complete occlusion of a bronchus preventing access of air into certain portion of the lung.

Jerk ing, interrupted respiratory sounds are often produced by animals voluntarily, from restlessness or fear. In such cases it is heard in both lungs. Pathologically it is confined to certain portions of a lung, and is observed when the free entrance of air into the vesicles is made difficult by a contraction or occlusion of the bronchi (bronchitis).

Bronchial respiration. The bronchial respiratory sound is normal in the larynx and trachea; its appearance in the chest is always a sign of disease. It is merely a laryngeal sound which is continued into the bronchi and is only audible when the bronchi are free and the vesicles contain no air.

Bronchial respiration displaces vesicular respiration:

if the vesicles are filled with exudate, therefore in all pneumonias, especially in contagious pleuro-pneumonia of the horse and in contagious pleuro-pneumonia of the ox. To be heard, however, the hepatized portion of the lung must be of the size of a double clenched fist and lie next to the costal wall.

if the lungs are compressed by pleuritic exudate (atelectasis). The compression must be complete, for if the vesicles contain air at all a feeble vesicular murmur can still be heard.

A special variety of bronchial respira-
tion is the *amphoric respiration*, which is a bruit, of a character like the sound produced by gently blowing across the mouth of a narrow necked bottle. In animals it is rare, but appears if large caverns in the lung communicate with bronchi (pulmonary gangrene). On percussion, in place of the dulled sound which is usual when the respiration is bronchial, a tympanitic tone or a cracked-pot resonance is heard.

That bronchial respiration may become audible the bronchi must not be occluded; if they are filled with masses of exudate, no respiratory sound is heard. A forcible cough, however, may dislodge and eject the exudate and the bronchi become free again.

**The vague or indefinite respiratory sounds.** Such sounds are spoken of when it can not be determined whether they belong to the vesicular or bronchial respiration. Either the sound is too feeble to be heard easily or other louder sounds drown it. Vague respiration is heard if hepatization is setting in, the vesicular murmur becoming weak and the bronchial sound just beginning. A slight compression of the lungs or partial occlusion of the bronchi with exudate may also produce it.

**Rales or rhonchi.** Rales are heard in disease and appear if the bronchi or a cavern in the lung contain exudate against which air is forced.

**Moist rales** appear if the bronchi contain a quantity of light, fluid exudation, (bronchitis). The larger the bronchi and the greater the quantity of exudate they contain, the larger will be the bubbles which are broken and the coarser the rales. In the large bronchi and in caverns, the rales may assume a gurgling or bubbling character. We also distinguish medium, coarse, and fine rales; the latter originating in the bronchioli. Rales may occur irregularly and are not always of like intensity. Sibilant rales are heard only at inspiration, increasing in intensity as the inspiration progresses; coughing may temporarily remove them. The intensity
of rales depends upon the extent of the disease and the topographical position of the diseased part.

Moist rales originate from the to-and-fro movement of mucus [pus, blood, liquid exudate], the forming and bursting of bubbles, and the vibrations produced by these acts. According to whether rales attend vesicular or bronchial respiration their tone will vary; metallic rales as a rule accompany bronchial respiration.

By crepitant rales, we understand very fine, crackling noises, which resemble the sound heard when the ear is rested very lightly upon the haired skin of an animal. Taking their origin into consideration they can be grouped with neither the moist nor the dry rales. They originate from a separation, at inspiration, of the adhering walls of the bronchi and vesicles. They appear in bronchiolitis, pulmonary edema and in the exudative (catarrhal) stage, and last stage (resolution) of fibrinous pneumonia (contagious pleuro-pneumonia of the horse).

Dry rales appear if a small quantity of a tough bronchial secretion is present, or if the mucous membrane is greatly swollen. These conditions produce stenosis of the bronchi, hence the sound is stenotic and of a sonorous, humming, hissing or whistling character. Dry rales most commonly attend chronic diseases: chronic bronchitis, compression of the bronchi by nodules (tubercles, chronic pneumonia) and tumors (echinococci). In the echinococcus disease of the ox the rale has a peculiar (quirksend) character.

A wheezing, crackling, whistling or piping, rale-like sound is heard in interstitial emphysema of the lungs. It is most pronounced during expiration.

Pleuritic friction sounds. Normally the pulmonary pleura plays noiselessly upon the costal pleura during the movements of each respiratory act. If, however, the pleurae become rough and dry from inflammatory deposits upon them, a sound is produced at respiration. This sound is best heard where the movement of the pleural laminae is greatest, therefore near the sharp borders of the lung. The intensity of pleuritic fri
tion sounds depends upon the extent of the disease [pleuritis]. They are audible as grazing or rubbing sounds just below the ear; if there is an intimate adhesion the sound is emitted in a series of jerking, creaking, or crackling noises.

A pleuritic friction sound appears in dry or fibrinous pleuritis only. It is most frequently heard in contagious pleuro-pneumonia of the horse and in contagious pleuro-pneumonia of the ox. It rarely occurs from the presence of tumors or neoformations upon the pleura. In tuberculosis, as a rule, no friction sound is heard.

Pleuritic friction sounds are easily confused with rales. Friction sounds are heard regularly at inspiration and expiration, may sometimes even be felt, and occur most frequently in a series of abrupt, jerking noises upon which cough has no influence. Rales are commonly more pronounced at inspiration than at expiration, are not jerking in character, and are removed or modified by cough.

Diseases of the Respiratory Apparatus.

a. Cavities of the Head.

Acute nasal catarrh. Rhinitis catarrhosa. Congestion of the mucous membranes, serous or mucous, rarely muco-purulent nasal discharge. Only when disease is severe is mild fever present; transient swelling of the sub-maxillary lymph glands.

Chronic catarrh of the superior maxillary and frontal sinuses. Symptoms of unilateral chronic nasal catarrh. When head is lowered discharge suddenly increases. Bulging of the diseased sinus; if filled with exudate empty sound on percussion.

Tumors in the cavities of the head. Most common are sarcomas in the sinuses and polypi in the nasal cavities. Chronic nasal discharge, enlargements, wheezing respiratory sounds, sub-maxillary glands also diseased.

Parasites in the cavities of the head. Larvae of Oestrus ovis in the sheep, pentastomum taenioides in the dog. Sneezing, nasal discharge, wheezing respirations, brain symptoms.
b. Larynx and Bronchi.

Acute laryngeal catarrh. Laryngitis acuta. Cough which is at first dry and painful, later more moist. When disease is severe: mild fever, accelerated pulse, dyspnoea with laryngeal stenotic sound.

Croupous laryngitis. Sudden fever, sometimes chills. Persistent, hacking cough. Loud laryngeal stenotic sounds, great inspiratory dyspnoea.

Oedema of the glottis. Suddenly appearing severe inspiratory dyspnoea, loud wheezing or shrieking respiratory noise, head held extended. Stenotic sound does not disappear by partially closing the nasal openings. Per-acute course.

Chronic laryngeal catarrh. Cough, especially when the animal is first brought out into the air and at work.

Roaring. Hemiplegia laryngis sinistra. An atrophy of the muscles of the larynx due to a paralysis of the inferior laryngeal nerve (recurrent), which causes an inspiratory sound. No fever, no catarrhal symptoms. Prolonged hoarse cough with return sound. Inspiratory sound when respirations are forced. Partial closing of the nasal openings causes sound to cease.

Acute paralysis of the larynx. Suddenly appearing severe inspiratory dyspnoea, which is apparent when the animal is at rest or slightly excited; loud whistling or shrieking respiratory noises, anxiety, restless-ness. Partial closing of the nasal openings diminishes the sound. General condition not disturbed.

Acute bronchial catarrh. May only be diagnosed when disease is well developed. Fever, accelerated pulse, dyspnoea, cough which is at first dry, later loose. Full sound on percussion. On auscultation, rales which depend as to character upon the seat and quantity of the exudate.

Chronic bronchial catarrh. No fever. As a rule a short, dull, weak cough. Dyspnoea not pronounced at rest; at work marked. Sometimes a fine-foamy, serous nasal discharge.

c. Lungs.

Pulmonary congestion and pulmonary oedema. Sudden appearance. Severe mixed dyspnoea up to 100 respirations per minute. Percussion normal, auscultation: exaggerated vesicular respirations, crepitant rales, rhonchi.

Pleurodynia. This is a congestion of the lungs combined with severe pains in the thoracic walls. General apathy, excessive dilatation of the thorax, which is "held." Groaning. Respirations 80 per minute, superficial. Temperature high-normal, pulse accelerated. Super-resonant sound on percussion, feeble vesicular murmur.

Catarhal pneumonia. Broncho-pneumonia. Begins usually as catarhal bronchitis. High, intermittent fever, painful cough. Only when disease is extended can pneumonia be appreciated; circumscribed patches of dulness on percussion; vesicular murmur feeble, rarely bronchial respirations.

Gangrene of the lungs. Fever. Expirium at first of a sickening, sweetish odor, later stinking. Discolored grayish-brown, tenacious nasal dis-
114  CLINICAL DIAGNOSTICS.

Alveolar emphysema. May only be diagnosed when well developed. Expiratory dyspnoea with "double-pumping" of the flanks, protrusion of the anus. Cough, short, dull, weak. Super-resonant percussion-sound, field of percussion enlarged posteriorly. Auscultation shows the vesicular murmur to be diminished.

Echinococcus disease. Ox. Diagnosis is only possible when large numbers of the echinococcus bladders are in the lungs. No fever. Dyspnoea. Cough weak and blowing. Percussion dulled in patches or tympanic. Vesicular respirations diminished.

d. Pleura.

Pleurisy. Pleuritis. Fever depending upon the character of the inflammation. Respirations accelerated and dyspnoeic. Frequent, painful, weak cough. Horizontal line of dullness on percussion above which a tympanic sound is observed. Percussion will vary with the position of the body of the patient. In early stages friction sounds are heard on auscultation, later when much effusion of exudate takes place no respiratory sounds are audible.

Pneumothorax. Attends interstitial emphysema of the lungs or penetrating wounds in the chest wall. Tympanic percussion sound in the upper portions of the thorax. Severe dyspnoea.

e. Infectious Diseases Which Involve the Respiratory Apparatus.

Contagious pleuro-pneumonia of the horse. (Brustseuche.) This is a contagious pneumonia affecting the parenchyma of the various organs and is usually attended with secondary pleuritis. 1. Stadium incrementi begins with high fever, yellow discoloration of the visible mucous membranes, general weakness, cracking of joints. 2. Acme. Does not appear before the second or third day. Symptoms of fibrinous pneumonia with or without pleurisy, usually unilateral. Rusty brown nasal discharge, empty percussion sound with resistance under the hammer, bronchial respirations. Pleuritis: Empty percussion sound limited by a horizontal line above which is a tympanic zone. Friction sounds which soon pass away, later no sound or bronchial respiration. 3. Stadium decrementi. The crisis appears in 7 or 8 days, temperature within 24-36 hours down to normal, all other symptoms, also pulse frequency gradually disappearing in 8 days. Complications: pleurisy, acute myocarditis. Resulting diseases: pulmonary gangrene, abscesses in the lungs, chronic pneumonia.

Scalma (Dieckerhoff) is a diffuse, infectious bronchitis with sub-acute course.

Tuberculosis. Tuberculosis is a contagious disease caused by the
bacillus tuberculosis and characterized by the formation of very small inflammatory centers which soon undergo degeneration. Only advanced cases can be diagnosed by physical examination. Dry cough, chronic lung trouble with gradual emaciation, percussion shows dullness in patches, also tympanitic sound. Exaggerated vesicular respiration, rales, piping and whistling tones on auscultation. Repeated mild bloating. Nymphomania, chronic metritis and mastitis in cows, enlargement of lymph-glands. See special examination for tuberculosis.

Strangles. Coryza contagiosa is an infectious catarrh of the mucous membranes of the upper respiratory passages with secondary, purulent inflammation of their corresponding lymph glands. Begins with fever of intermittent character. Pulse at first little increased but may reach 80. Nasal discharge serous, mucous or purulent, usually bilateral and profuse. In 3 or 4 days at latest inflammatory swelling of the sub-maxillary lymph glands, which in 4 to 8 days later have abscesses formed in them. Pharyngitis frequently concomitant. Dysphagia, abscess formation in the subparotid and retro-pharyngeal lymph glands. If larynx is involved: cough, loud inspiratory noises. In old horses disease often limited to the pharynx.

Glanders, malleus, is a contagious disease of solidungula, caused by the Bacillus mallei, characterized by the formation of nodules and abscesses in the respiratory mucous membrane and skin. On the nasal mucous membrane we find gray nodules as large as millet seeds, transparent and surrounded by a red zone. The nodules become yellow, degenerate, form ulcers with raised and jagged borders and lardaceous bottom. Nasal discharge slight, frequently unilateral, varyingly sticky, slimy, purulent, occasionally discolored and bloody. Intermaxillary lymphatic glands enlarged, knotty, firm, adhering to bone or skin. In skin and subcutis rather flat, painful, hot nodules varying in size up to that of a hen's egg, these break, discharge discolored pus and become ulcerous. Lymphatics efferent and afferent to these nodules are enlarged to thickness of a finger. See also specific examination for glanders.

Contagious pleuro-pneumonia of cattle is a contagious croupous interstitial pneumonia. We distinguish an occult stage which is marked by a slight cough, fever, and slight dyspnoea. In the acute stage we have distinct fever—41°C [105.8°F] and the symptoms of an acute pleuro-pneumonia. Great dyspnoea, weak, short cough, some nasal discharge, extended empty sound on percussion, friction bruits, bronchial respiration, rales. Appetite, rumination and secretion of milk suspended.

Malignant catarhal fever is a specific disease of the ox, has a subacute course and affects chiefly the respiratory and digestive mucous membranes, and the brain. Disease is introduced with chills. Great mental depression, muscular trembling, stiffness, sometimes inability to stand. Conjunctivitis and keratitis. Diphtheritic inflammation of the mucous membrane of the nose, sinuses of the head, trachea and mouth, rattling, wheezing and breathing. No appetite, secretion of milk suspended.

Distemper of dogs is a very contagious disease that is characterized chiefly by catarhal affections of the mucous membranes. Symptoms quite varied; we distinguish: catarhal, nervous and exanthematous distemper. Symptoms of the disease develop slowly. Animals are indisposed, conjunctivitis, keratitis, vomiting, disturbed appetite, slimy nasal discharge, cough, dyspnoea, tympanitic and occasionally dulled sound
on percussion of lungs, rales. Spasms affecting the whole body or only certain groups of muscles, general muscular weakness, paralysis. Vesicular and pustular exanthema.

8 Digestive Apparatus.

Diseases of the digestive apparatus are common in domestic animals. Their diagnosis is, in some respects, far more difficult than that of the respiratory apparatus because the organs in the former case are not as accessible to examination. For this reason every possible factor must receive most careful consideration. We observe them in the following order:

I. Food and Drink.
II. The Buccal Cavity.
III. The Pharynx and Oesophagus.
IV. Rumination.
V. Vomiting.
VI. The Abdomen.
VII. The Intestinal Evacuations.

I. Food and drink. Before examining the various organs of the digestive apparatus, we must note the animals appetite for food and drink and also the character of these latter, also observe the way in which the animal takes its food, masticates and swallows it.

Appetite for food. The degree of appetite that an animal displays toward a certain food depends on the palatability of the food and also on the degree to which the animal has accustomed itself to it. This must always be borne in mind when probing for the cause of poor appetite, and hence an inspection of the food must not be neglected. Individual appetites vary widely. One horse may be a good feeder, another a poor feeder, both may enjoy perfect health. High strung horses often refuse their food after active exercise, but their appetite returns after a short rest. A change of stable or unaccustomed loneliness has a marked effect on the appetite of some sensitive horses. Of the various grains horses prefer oats and Indian corn and of the grasses sweet timothy or meadow hay. Oats is by far the most suitable grain to feed a horse.

In all serious cases of disease the appetite is more or less affected, hay or straw are usually the last part of the ration refused. Defective appetite alone is never an
udication of any particular disease. As a rule, complete loss of appetite is an unfavorable symptom; on the other hand, a good appetite in the course of a severe disease may be regarded as a favorable symptom.

Desire for water depends in the first place on the amount of water contained in the feed; dry feed requiring more water than green feed; of course some water is required in both cases. The demand is also affected by the amount of water given off through the skin, kidneys and intestines. Many horses are very sensitive in the matter of impure water, some even refuse "pure" water if of a different kind than that to which they have been accustomed [e. g. spring water and rain water].

The desire for water is diminished in colic and in all serious gastric and intestinal affections, providing no diarrhœa exists; horses with acute cerebritis also refuse water. Continued refusal of water is on the whole considered as an unfavorable sign; when horses with colic drink water it is regarded as a favorable sign.

Thirst is increased in the course of various diseases:
1) animals with fever like small sips of fresh water at frequent intervals;
2) when the crisis occurs in influenza or contagious pleuro-pneumonia of the horse, increased renal secretion and thirst go hand in hand;
3) exudative pleuritis and peritonitis;
4) diabetes insipidus of horses is attended with marked increase of thirst; several pailfuls are taken at a time;
5) gastric and intestinal catarrh [diarrhœa] of dogs—attended with frequent vomiting.

By the term perverted or depraved appetite we mean the craving of unnatural food by otherwise healthy [?] animals. As a rule this is a very important symptom. Of course this condition must not be confounded with playfulness of young animals which gnaw at, bite and even swallow almost anything
of convenient consistency and size. Thus cattle will lick at
ones clothes, dogs eat blades of grass.

*A craving for alkalies* is pathological: e.g. straw soiled
with urine and feces, whitewash etc. on walls, wood; acids in
dyspepsia.

*Swallowing indigestible substances*, like cloth, leather,
wood, stones, and similar objects is observed in lick disease of
cattle, and wool eating of sheep; in rabies the same vice is ob-
served.

**Manner of taking food.** Healthy horses grasp the food with
their lips and pass it into the mouth, then with the aid of the
tongue and cheeks it is forced between the molars. Sheep and
goats do likewise. Healthy cattle grasp their food with the
extended tongue, curved like a hook.

In horses the following changes are observed:

1) in inflammatory swelling of lips and cheeks as well as
in paralysis of the cheeks (facial or 7th nerve), horses take up
their food with their *teeth* and experience difficulty in getting
it into the mouth.

2) in cerebral depression they show similar peculiarities;
while drinking they may insert the nostrils below the level of
the water and "masticate" it;

3) in tetanus feeding is very laborious; mastication and
suction movements are impossible because the spasmodic con-
traction of the masseter muscles has closed the buccal cavity.

In cattle normal feeding is disturbed in inflammatory
affections of the tongue (actinomycosis), this organ often be-
coming hard and rigid (woody tongue). Cattle thus affected
grab their food like dogs.

The manner of drinking water must also be
observed. Normally only dogs and cats lap their drink.
When the facial nerve is paralyzed animals must insert the
whole mouth into the water so that they can get it near
enough to the pharynx to swallow it.

**Mastication.** The briskness with which this act is performed
bears a direct relation to the palatability of the food and the
appetite of the animals; healthy horses and cattle make 60-100 masticatory movements per minute.

Masticatory movements are conspicuously retarded in cerebral depression, in the course of severe fevers, and in acute and chronic hydrocephalus. The animals cease masticating for some time, seem "absent minded," and forget to eat. This often happens while the mouth is full of feed, and pieces of hay and straw sticking out of it.

Mastication is made difficult in paralysis of the facial nerve; here the food collects in large masses in the lower part of the mouth; it is also observed in tetanus or spasms of the masticatory muscles due to other causes.

Mastication is impaired and laborious when mechanical defects of the teeth exist. Shear jaws, and irregular teeth, projecting teeth, etc. The animals masticate one-sided, cautiously and "easy;" they don't masticate thoroughly, the food is "crushed and bruised" but not "ground."

Mastication is painful when acute inflammatory conditions exist in the cheeks, temporo-maxillary articulation and in the intermaxillary space as they occur in the course of distemper of horses. Mastication may be voluntarily interrupted. If sharp or pointed objects like nails, needles, splinters of wood, etc., are taken up with the food horses open their mouths wide and allow the contents to drop out, aiding with the tongue. They do the same thing when injuries are produced by sharp teeth or displaced teeth (alveolar periostitis); sudden pain, produced by biting on a diseased or loose tooth, produces the same effect. Horses with diseased teeth frequently drop small masses or balls of food into the manger, "quibbing". Some horses suddenly raise their head while masticating and hold it sideways, open the mouth and continue masticating in a cautious manner, at the same time making slow lateral movements with the lower jaw. Varied as the symptoms that occur in the course of different affections of the teeth may be, they all have one
thing in common, they make mastication difficult and painful.

In dangerous diseases we often observe gnashing of the teeth, at the same time this is not a "prognostically unfavorable" sign.

**Difficulties in deglutition.** Deglutition is the closing act of feeding. It is described as occurring as follows: The lips are closed and the jaws are set together, then the tip, the back and the base of the tongue are successively pressed against the palate and thus the contents of the buccal cavity are forced into the pharynx. By contraction of the muscles of the pharynx in front of the food mass the peristaltic motion thus inaugurated carries the bolus into the esophagus. At the same time the pharynx is slightly raised and the pressure exerted on the epiglottis by the base of the tongue, which projects backward, closes the larynx and allows the food to glide over it. The nasal openings leading into the pharynx are closed during this act by a raising of the soft palate and a coming together of the borders of the posterior pillars of the fauces brought about by contraction of the muscles of the pharynx.

A disturbance of normal deglutition is most frequently caused by inflammatory processes in the pharynx that cause infiltration and disturb the function of the local muscles. The result is not only a painful condition during swallowing but the closure of the larynx or nasal cavities may be incomplete. Accordingly we may observe manifestations of pain, extended head and neck, the animals often shaking their heads. Incomplete closure of the pharyngeal openings results in food particles entering the larynx or nasal cavities and giving rise to cough, or ejections of water, saliva or food through the nostrils (regurgitation), as the case may be. The degree to which the closure of the pharyngeal openings is imperfect, bears a direct relation to the severity of the affection. In mild cases, fluid only is regurgitated, noticeable while drinking water. Later on as the case becomes aggravated, solids also pass out. When the affection
is mild and restricted to one side the regurgitation may also be unilateral. Soft feed is more apt to cause regurgitation than are solid substances. An inflammatory affection of the pharynx that causes difficulties in deglutition may be primary, (pharyngitis), or secondary to other diseases: distemper, morbus maculosus, anthrax.

In addition, difficult deglutition is observed in:

1) paralysis of the pharynx in mycoses, parturient paresis, and rabies;
2) spasm of the pharyngeal muscles in tetanus;
3) tumors of the pharynx; actinomycoma, lymphoma.

Besides the symptoms of difficult deglutition we observe in addition: salivation, foaming at mouth, ejecting food from mouth while coughing, retention and fermentation of food in mouth cavity.

Fig. 28.

Inspection of the Mouth Cavity.

II. The buccal cavity. We usually examine the buccal cavity by daylight and without the aid of instruments; artificial illumination with reflectors, lamps, or electric lights is sometimes useful but not necessary.
Method of examination. In the horse and ox the hand is passed into
the mouth at the bars, the tongue firmly grasped, and the thumb pressed
against the palate. This procedure will, as a rule, cause the animal to
open its mouth wide. Another practical method consists in grasping
with the hands, on both sides, the upper lips at the commissures and
resting the thumbs against the palate. In dogs and cats we grasp, with
our hands, on both sides, the upper lips at the commissures and
resting the thumbs against the palate. In dogs and cats we grasp, with
our hands, on both sides, the upper and lower jaws, at the same time pressing the lips
between the teeth; hereupon the animal opens its mouth wide enough to
permit inspection.

Restless animals must first be secured and then towels or cords are
passed between the dental arches, and by means of these the jaws are
forced apart.

In examining the mouth the following should be ob-
sewed:

The temperature is elevated in fever and in local inflam-
mations of the mucous membrane, stomatitis and also pharyn-
gitis.

Secretion of saliva. Secretion is diminished in
all acute febrile diseases, severe intestinal affections, and, as a
rule, in colic.

An abnormal quantity of saliva in the mouth
results either from the fact that the animal does not swallow
the normal secretion (dysphagia) or that an abnormal secre-
tion has occurred, as in simple catarrhal or traumatic stomat-
titis, diseased teeth, foot and mouth disease, stomatitis pustu-
losa contagiosa, malignant catarrh, mycoses, etc. The saliva
passes off in the form of clear strands or in the form of foam
produced by masticatory movements. In epilepsy this foam
is observed at the commissures of the mouth.

Odor from the mouth. An "insipid sweetish" odor is ob-
served when decomposing food-particles, epithelial cells or sa-
liva in the course of stomatitis catarrhalis, are present. A pu-
trid odor is produced by decomposition of nitrogenous sub-
stances. Exudates are present in malignant catarrh and stomacace in dogs. A carious odor is produced by suppurative
processes in bones, especially in alveolar periostitis.

Specific morbid conditions. Clamminess of the buccal mucous
membrane occurs in digestive disorders (loss of appetite); red-
dening and swelling of the mucous membrane with loss of sub-
stance is observed after the action of irritants and caustics [chloral hydrate pills]. Simple catarrh is attended with similar but milder symptoms.

*Punctiform hemorrhages* occur in morbus maculosus and leucæmia. *Nodules, pustules and ulcers* in stomatitis pustulosa contagiosa; *Ulcers* on the gums in stomatitis ulcerosa, calf diphtheria, swine plague, mercury and lead poisoning. *Blisters* in foot and mouth disease, small isolated yellowish *vesicles* in stomatitis vesicularis. *Wounds* at the tongue tip and frenulum are produced by rough handling of the bridle bit; sharp teeth produce wounds on the inside of the cheeks, and sides of the tongue.

**Foreign bodies** are of frequent occurrence in horses [corn cobs], dogs, and cats, rare in other animals; they consist of pieces of bone, needles, etc., occasionally ring-like objects slip over the tongue accidentally: e. g. cross sections of the aorta, intestines, trachea, iron rings, etc., [rubber bands slipped on intentionally by children during play]. The symptoms are; open mouth and salivation, attempts at removal on part of the animal, eating and drinking interfered with, the tongue swollen.

Careful manual as well as ocular examination is often necessary to recognize these conditions.

**Condition of the teeth.** Examination of the teeth of horses is of particular importance on account of the frequent occurrence of diseases and malformations of these organs. In dogs diseased teeth are also common.

Abnormal position of the incisors (parrot mouth and pike mouth) point to the existence of a similar defect in the molars. Parrot mouth is not an uncommon occurrence in high bred colts. In ruminants the incisors are normally loose. Carious incisors and molars occur in dogs in the course of rachitis, distemper, anaemia and stomacacce.

Careful examination of the molars, with
the aid of a speculum* is indicated when horses reject food after partial mastication, when they show any abnormal masticatory movements, and when large quantities of coarse food particles occur in the droppings. The friction surface and the lateral faces of the teeth can be examined simultaneously by letting the index and middle fingers glide over the former, the thumb and the remaining fingers over the latter. Abnormal conditions of the teeth can usually be felt far better than they can be seen. We should observe the presence or absence of sharp points, slanting friction surfaces, shear jaws, interrupted jaws, projecting teeth, short teeth, carious and broken teeth, cavities, etc.

III. Throat and oesophagus. Examination of the throat and oesophagus is restricted to external inspection and palpation.

Inspection. Diffuse swellings in the region of the pharynx occur in phlegmonous conditions of the mucous membranes (pharyngitis). Circumscribed swellings indicate the presence of abscesses and tumors.

Palpation. Increased temperature and sensibility indicate acute inflammation which may be either diffuse (pharyngitis) or circumscribed (development of abscesses). The consistency is firm, yet yielding; even in abscess formation distinct fluctuation is rarely present here. Circumscribed painless swellings of firm consistency indicate the presence of tumors, usually melanomas in old gray horses and actinomycoma in cattle. Palpation of the oesophagus serves to detect the presence of foreign bodies, mostly observed in cattle in the form of pieces of potatoes, apples, corn cobs, etc. Esophageal diverticula and stenoses cause periodically recurring occlusions of the oesophagus. Ingestion of food causes the oesophagus to distend—sausage like. Such animals cease eating, or, when they attempt to

*For horses a speculum is not in all cases necessary for the detection of defects or other abnormal conditions of the teeth. By passing the hand into the mouth at the bars, at the same time pushing the tongue to the opposite side that organ is forced between the molar teeth on that side and the animal will voluntarily keep its jaws sufficiently separated to permit examination of the condition of the teeth without endangering the safety of the operator. The right molars are examined with the right, the left with the left hand, the operator facing the animal.]
eat or drink, regurgitation through the nostrils of the ingested mass takes place.

Examination with a probe or probang has no special value; the dilated oesophagus, regurgitation, vomiting of food and symptoms of choking are sufficient to base upon them the diagnosis *diverticulum and stenosis*, two conditions usually coexisting. On the other hand, the fact that a probang can be passed freely through the oesophagus does not exclude the presence of these conditions.

**IV. Rumination.** Rumination is a specific physiological act of the digestive apparatus of ruminants. These animals feed by taking up food hurriedly and swallowing it after little or no mastication. After ingesting a sufficient amount of food in this manner, the latter, which by this time has become partly macerated by the saliva which accumulated with it in the rumen, is carefully *remasticated*. During this act the animals prefer a recumbent position. The food is forced into the mouth by a contraction of the second stomach or reticulum into which it previously passes from the rumen. Every *cud* is subjected to about 60 masticatory movements and is then *re-swallowed*, this time passing directly into the omasum and abomasum or true stomach through the oesophageal groove. The whole act of rumination requires from one to two hours. When cattle are driven or oxen put to work before they had time to finish ruminating, this act is temporarily suspended to be resumed at the next period of rest.

Slight disturbances of the act of rumination can as a rule not be recognized as such.

Considerable deviations from the normal or complete suppression of rumination alone are definite signs of disease.

In the beginning disturbances in rumination due to disease manifest themselves by a reduction in the number of *cuds* chewed in a certain time, by the number of masticatory movements applied to each cud before being swallowed and by the rapidity with which the animal masticates.

The severity of the disease corresponds to the degree to which rumination is interrupted. In severe diseases rumination ceases entirely.

Rumination is disturbed in:

a) [all severe febrile and painful affections, surgical diseases.]

b) gastric and intestinal disturbances, especially over-
loading and paralysis of the paunch.

c) traumatic inflammation of the stomach and diaphragm.

d) [all cachectic diseases.]

e) [many cerebral diseases.]

**Eructation** or belching occurs normally in ruminants only. This consists in audible expulsion of paunch gases through the oesophagus and mouth. [Eructations become distinctly audible and abnormally frequent during fermentation processes in the paunch, slight tympanitis, etc. Sometimes they are accompanied by disagreeable odors (fermentations) but the character of the food also plays a role here (onions).]

**V. Vomiting.** Vomiting is a reflex (involuntary) spasmodic evacuation of the stomach or paunch contents through the mouth or nasal passages. This act is assisted by simultaneous contraction of the abdominal and inspiratory muscles. Immediately preceding the act of vomiting animals make a deep inspiratory movement. Vomiting is caused by indirect (rarely direct) stimulation of the vomiting center in the medulla oblongata.

The ease with which vomiting occurs in our domestic animals varies with the species according to the anatomical construction and the degree of fullness of the stomach. Carnivora, pigs, and birds vomit most readily and with greatest ease, ruminants less so. Horses rarely vomit. This is explained by the anatomical structure and position of the stomach. [The stomach of the horse is comparatively small and even when filled does not always come into contact with the floor of the abdomen, hence is not easily affected by abdominal contractions.]

Further, the spiral arrangement of the muscular coats, insertion of the oesophagus at the middle of the stomach, its contracted and thickened wall at the point of insertion (in contrast to the funnel shaped thin walled structure of this organ in other animals) and the large fundus of the horse's stomach must be considered in this connection.

A vigorous contraction of the stomach will serve to over-
come these obstacles and vomiting may occur in the horse. In such cases, however, there is always danger of rupture of the organ. This is the usual result when the stomach is well filled with food. Vomiting in the course of colic is therefore always a serious symptom. If, however, the stomach of the horse is moderately filled with fluid contents, a rupture need not occur. In such cases the act of vomiting is usually not caused by an overloaded stomach but by direct stimulation of the vomiting center. (Chloroform narcosis, hemorrhages and inflammations near the medulla).

Vomiting is always a symptom of disease and occurs under the following conditions:

a) during the presence of foreign bodies in the larynx or at the base of the tongue: pieces of bone, fish bones, needles, feathers, etc., also when tough, stringy mucus collects in this region in the course of pharyngitis and laryngitis;

b) obstruction of oesophagus;

c) gastric affections, overloading of stomach, gastritis, and in certain poisonings;

d) intestinal affections, such as prevent the normal progress of food masses through the lumen of the intestine and thus provoke antiperistaltic movements which cause the stomach to become distended with intestinal contents, irritation of its mucous membrane, and vomiting.

The character of the vomited material may often serve to determine the cause of the act and the origin (stomach or intestine) of the ejected mass.

VI. The Abdomen. Examination of the abdomen is conducted according to the following general rules.

Inspection. The volume or circumference of the abdomen in domesticated animals is subject to great variations and great care must be exercised here in diagnosis. For clinical purposes the size of the abdomen must always be considered in connection with the general condition of the animal, its general make up, feed, care, etc. Animals habitually kept on voluminous food in ample abundance develop a voluminous abdomen. A
good plan is to inquire of the owner as to the former or usual condition of the animal in this respect. Circumscribed enlargements are usually of interest from a surgical point of view.

Abnormal distention of the abdomen may be due to:

a) pregnancy: the form of the abdomen becomes barrel shaped—increasing bilaterally.

b) accumulation of abnormal quantities of food in the digestive tract (in horses the caecum and colon, in ruminants the paunch and other stomachs, in dogs the stomach). In these cases the distention is due either to increased consumption of food (overfeeding) or to accumulation of food taken in normal quantities during inactivity of the bowels (constipation). In these cases the normal tympanitic tone is replaced by a dull one.

c) the accumulation of gases produced by fermenting food. In this case the distention is in an upward direction, the hollow of the flank is raised, and the abdominal walls become distended (tympanitis, bloat). The rapid production of gas may be due to the character of the food [legumes, crucifera, etc.] or to suspended activity of the bowels.

d) accumulation of fluid (transudate and exudate) in the peritoneal cavity. This is occasionally seen in dogs, rarely in horses. In this case the distention is in a downward direction, symmetrical and bilateral, fluctuation is observed and percussion reveals a dull area bounded above by a horizontal line. When a dog thus affected is raised to a vertical position the dull area is shifted (ascites).

e) tumors in the abdomen; liver (ecchinococci and carcinoma), spleen (leucaemia), glands, etc.

f) dropsy of foetal membranes.

Abnormal reduction in size of the abdomen may be due to:

a.) long continued starvation, or, if in spite of good care, abundant food and sufficient rest an animal shows this symptom we may conclude that lack of appetite is at fault (digestive disorders).
b.) *in serious subacute diseases;* in such cases the animals general condition may still be good.

c.) *during or following severe diarrhoeas,* or after colic when strong purgatives were prescribed.

d.) *violent contraction* of the abdominal muscles in painful affections of the hind legs.

**Palpation.** The object of palpation is to ascertain the consistency of the bowel contents and whether or not painful conditions exist. In ruminants the peristaltic motion of the

![Diagram](image)

H. Reticulum; L. True Stomach; — — Liver; \( \nabla \) Area of Percussion for the Lung.

paunch can also be observed by palpation. Palpation of the bowels per rectum is of especial value in large animals.

In horses the abdominal walls are thick and tense; this and the fact that during an examination the animals frequently contract their abdominal muscles increases the difficulty of arriving at accurate results as to judging of the condition of the abdominal organs, their contents, etc. In cattle the abdominal walls are thinner, hence the results of palpation are more accurate and satisfactory; in sheep this is true to a still greater degree.
Dogs habitually contract the abdominal walls when these are manipulated but soon relax them again. In dogs both sides are palpated simultaneously, and by exerting pressure from both sides toward the median line the entire abdominal cavity may be thoroughly examined.

Palpation serves in the first place to inform us as to the degree of contraction (the tenseness) of the abdominal walls and the consistency of the bowel contents; the latter should be soft and easily compressible. If impressions are made by pressure they should soon be effaced by the effects of peristalsis. Large quantities of fluid bowel contents produce fluctuation. Neoformations (tumors) are recognized by the extreme resistance they offer to pressure. In dogs accumulated fecal masses [and intussuscepted intestines] can readily be felt. Foreign bodies in the stomach and intestines can also be detected by palpation providing the normal bowel contents are previously evacuated [medicines or clysters].

Another object of palpation is to ascertain painful conditions or abnormal sensitiveness. Even healthy horses are often extremely sensitive to pressure exerted on the abdomen and become restless when subjected to such an examination. Care must therefore be observed not to mistake these symptoms for something more serious. In cattle it is different, because abnormal sensitiveness in these animals always points to the existence of important lesions.

Sensitiveness to pressure between the 6th and 8th ribs (opposite the reticulum) points to the possibility of an injury to the diaphragm from a foreign body that penetrated the reticulum. In acute affections of the true stomach cattle evince symptoms of pain on palpation of the hypochondriac region. Palpation of the right flank in cattle, when intussusception of the small intestine exists, is also attended with symptoms of pain. Foreign bodies in the intestines of dogs produce symptoms of pain when pressure is exerted.

In cattle the peristaltic movements of the paunch are an
important consideration. Normally these can be felt in the
cavity of the left flank at the rate of about two per minute.
The food masses are moved from below upward and toward
the right side. Every contraction of the paunch is attended
by a slight rise in the cavity of the flank followed by a some-
what more sudden drop or depression. Imperfect or slowed
movements of the paunch point to the existence of some patho-
logical condition (overfeeding, tympanitis, paresis of the
paunch, peritonitis, adhesions of the paunch with the abdomin-
al wall).

Palpation of the bowels per rectum. This is possible only
in the comparatively large rectum and roomy pelvis of the
horse and ox, but on the other hand the proportions are so
large here that only a part of the abdominal region can be thus
explored. In the region within our reach we can determine
position and contents of the abdominal organs, also the pres-
ence of foreign bodies and tumors.

Method of procedure. To make a thorough examination it is
often necessary to introduce the arm its full length. A shirt
without a sleeve can be worn to advantage on such an occasion.
[After carefully paring the finger nails] the arm should be
well covered with oil, or soap (castor oil answers the purpose
well) and then, with the tips of the fingers forming a cone,
the hand is carefully introduced into the rectum. During the
examination the animal’s head (if a horse) is held up, and the
forefoot on the side where the operator stands is raised, by an
assistant. Nervous or excitable horses can be secured with a
twitch or the operator can protect himself against kicks by
having the animal standing close to a stable partition, the op-
erator standing on the opposite side. The left half of
the abdominal cavity can be examined most satisfacto-
riely with the right hand, the right half with the left hand.
Since perforations can be produced it is advisable to proceed
with the utmost care in making rectal examinations.

If accumulated food masses, contraction of the rectum, or
the presence of gases retards the easy introduction of the hand
simultaneous infusions of water should be given to facilitate the operation. It is always a good plan to insert the arm nearly its full length, before beginning our examination. In this way a long piece of the rectum slips over the arm and there is less danger of pulling or straining the mesentery. This danger decreases as the length of the mesentery increases anteriorly.

Exploration per rectum is indicated in chronic colic and in all cases of colic in stallions and cattle. Palpation may serve to determine the following points:

1. Fullness and position of the bowels

The separate regions of the intestines can be definitely recognized only when they are filled with food. Mere distention with gases does not always enable us to recognize with certainty the identity of parts. When the bowels are empty or only partially filled with fluids or gases it may be impossible to distinguish between the large and the small intestine. The longitudinal muscular bands of the large intestine of the horse are the only means of differentiation, and these must be sought. Manual exploration per rectum enables us to recognize food accumulations or impactions in the following divisions of the bowels.

1) Impaction of the floating colon. This is of frequent occurrence in its posterior region and can then be easily recognized (rectal paralysis); constipation in the floating colon is recognized by the nodular character of the surface and the sinuous course of the bowel. Its volume is appreciably less than that of the colon or caecum.

2) Impaction of left colon. When well filled with impacted food masses the pelvic flexure projects into the pelvic cavity and frequently toward the right hand. This flexure is recognized by its great volume, its curvature and the short mesentery uniting the two superposed layers of the left colon.

3) Impaction of caecum. The base of the caecum is situated in the upper portion of the right flank and is attached to the spinal column by means of a mesenteric fold and the pancreas.
When distended with food-masses its great curvature, which is smooth, projects almost to the right hand border of the pelvis. The small curvature can also be recognized and serves to identify the organ. The longitudinal muscular bands can also be felt.

4) Impaction of the ileum. This usually occurs near the ileo cecal valve. The impacted intestine courses transversely from the left to the right side of the flank. It can be recognized by its sausage-like form which can be almost encircled by the hand.

The following dislocations or displacements of the intestine can be diagnosed.

a) Incarceration in inguinal canal; most frequently observed in stallions. The intestine can be felt about two or three inches in front of the pubic bone and four or five inches to the right or left of the median line where it seems to be firmly attached. A pull exerted at this point causes the animal to evince signs of pain. Simultaneous examination of the scrotum (external) clinches the diagnosis.

b) Peritoneal hernia or so-called gut tie of the ox. A loop or knuckle of intestine can be felt at the anterior margin of the ileum, retained between the latter and the vestige of the spermatic cord. The doughy painful swelling, held in position by the tense cord which is situated anteriorly, are the characteristics of this condition.

c) Invagination of the small intestine in cattle. This condition is recognized by the presence of a firm but elastic sausage-like mass in the lumen of the intestine, terminating abruptly posteriorly but insensibly anteriorly where food masses have accumulated. The length of this mass varies with the extent of the invagination.

d) Torsion of the left layers of the colon in the horse. In this condition the tense mesentery can be felt coursing downward and to the left immediately in front of the entrance to the pelvis and just below the 4th lumbar vertebra. A pull exerted on the mesentery produces symptoms of pain. A second tense strand can be felt in the umbilical region (a longitudinal
band of the inferior layer of the colon which courses from left to right). The pelvic flexure has shifted from its normal position.

II. *Enteroliths* (stones and concretions in the intestines) can be detected only when the intestines are comparatively empty. The presence of large masses of food interferes with their recognition. It is best, therefore, when these are suspected, to free the intestines of their contents with a purge before proceeding with the examination.

III. *Tumors* and tuberculous tumefactions of the lymphatics can be recognized only when they have a certain size, e.g. that of a hazelnut, and here too a purge must be given to remove solid fecal masses before exploration begins, otherwise mistakes are easily made.

**Percussion of the abdomen.** As a rule the stomach and intestines contain a moderate quantity of gases which distend their walls *only slightly*; hence percussion produces a tympanitic sound. In the paunch of cattle and the large intestine of the horse where food masses accumulate, the sound is at times dull tympanitic or even dull. (Topography of bowels at left side in the horse; see fig. 25).

Abnormal accumulations of food masses in the cæcum and colon give rise to a dull sound and a sensation of resistance to the finger or pleximetric hammer at points on the abdominal wall opposite them. If the accumulation of gases causes the bowel walls to distend abnormally and become *tense* a clear sound is produced, a sound resembling that produced by the healthy lung, only clearer and louder because large air chambers are present. (In the lungs the air chambers are small).

Bilateral dullness, limited above by a horizontal line is observed when fluids collect in the abdomen (ascites). This is most frequent in the dog; raising the animal to a vertical position shifts the dull area accordingly.

**Auscultation of the abdomen.** The observation of the various sounds produced by the moving along of the intestinal con-
Digestive Apparatus.

135

tents has for its objects the determination of the character of the movements of the bowels. The sounds are produced by the onward movement of the solid, liquid and gaseous contents of the bowels. The gases particularly produce distinctly audible sounds. In the absence of intestinal contents sounds are not produced by peristaltic motion.

The character of the sounds is determined by the consist-

Fig. 30.

B Caecum; U Inferior layer of colon; O Superior layer of colon; \(\n\) Limit of percussion area of lung.

ency of the intestinal contents and by the quantity of gases present. Hence: the sounds of the small intestine are those of flowing liquid, gurgling, and splashing; the sounds of the large intestine rumbling, cooing, and tumbling.

The intensity of the sounds corresponds to the intensity
of the bowel movements, and we distinguish, lively, weak, hardly audible, short and prolonged sounds or noise.

None of the intestinal sounds are continuous, they are always interrupted by quiet intervals, but in healthy animals these intervals are never long. Practice in auscultation is of course necessary to enable us to judge correctly.

In diseases quantitative as well as qualitative deviations from the normal occur. The sounds may be absent altogether in certain regions, e.g., the small intestine may have a lively peristaltic motion while the large intestine remains at rest.

Intestinal sounds are reduced or diminished:
1) in impaction, constipation and tympanitis, a paralytic condition resulting from over distention and overloading (colic).
2) in spasmodic contraction of the small intestine in the course of spasmodic and rheumatic colic.
3) in persistent diarrhoea when the intestinal contents are scanty.
4) in severe inflammatory conditions (because peristalsis is then more or less suspended and the intestinal contents are scanty (enteritis, peritonitis).

Very lively and loud intestinal sounds occur in all cases of slight stimulation, especially when the latter is produced by laxative food: green fodder, raw potatoes, wheat bran [clover hay, alfalfa, etc].

The sound of a drop of water falling onto a metal plate or pan is sometimes observed and belongs to a class by itself. It occurs when a loop of intestine is greatly distended and the fluid contents of the overlying intestines (small intestines) is forcibly flung against it and causes its walls to vibrate. The presence of this sound indicates that a loop of intestine is at rest and that it is distended with gas.

VII. Intestinal discharges or evacuations. The quality and quantity of the discharges depend in the main on the kind and quantity of the food. The amount of water imbibed has little or no influence on the consistency of the discharges.
The beginner must make an objective study of the character of the discharges of different animals on various foods, and in particular cases make comparisons with the discharges of other animals kept under the same conditions in the same stable. There are many diseases in which the character of the bowel discharges is of very great importance.

Defecation. Defecation is difficult when the feces are dry or hard (constipation). Continued rest after, and during heavy feeding may lead to an accumulation of bowel contents or even to constipation. Voluntary defecation is almost impossible when paralysis of the rectum exists, in such cases the agitation of the body during locomotion causes the feces to be passively discharged through the gaping anus.

Involuntary evacuations of the bowels occur in cerebral spasms and in paralysis or relaxation of the anus. The latter is common in the course of severe diarrhoeas, here the semi-liquid feces flow down on the legs.

Defecation is painful in the course of painful inflammatory conditions in the abdominal cavity (intestine, peritoneum), diaphragm or abdominal walls. These conditions all interfere with the normal contraction of the abdominal muscles during the act of defecation. In dogs foreign bodies (bones) in the intestines, and obstructions by agglutinated hair at the anus of long haired dogs, are particularly troublesome. The patients groan, cry or howl during attempts at defecation; they avoid the act as much as possible and thus bring on constipation.

Frequency of defecation. Carnivora defecate once or twice daily, herbivora much more frequently; horses 8-10 times, cattle 12-18 times. These figures are increased by bodily exercise—particularly in horses that travel much.

When the normal frequency of defecation is reduced, we say the animal is constipated. This is mostly the result of diminished peristaltic motion which is also attended with increased absorption of fluids. Constipation may result from impaction, occlusion, and dislocation of the intestine, first
stages of intestinal catarrhs, inflammations, etc. Constipation is the principal symptom of colic, it may occur, however, without any other colic symptoms. In ruminants the ingesta are usually retained or retarded in the paunch and oomum, rarely in the intestines.

The term diarrhoea is applied to frequent and usually copious evacuations of liquid or semi-liquid feces; it occurs in all irritated conditions of the intestinal mucous membrane and is caused by feed, catarrh and inflammation. Psychic disturbances may lead to diarrhoea by reflex action.

**Volume of feces.** Here we must distinguish between the amount passed at a single defeation and the total for a day. Well fed horses (stable) pass 2 to 4 lbs. at each act, 20 to 30 lbs. per day. In acute and in chronic hydrocephalus the volume of the evacuated masses as well as the intervals between evacuations is increased. The evacuations are increased in quantity in diarrhoea following constipation, and after the use of evacuants they are diminished after [prolonged diarrhoea], during constipation and when animals are underfed.

**Consistency and form.** Under normal and usual conditions horses' dung is evacuated in balls of a regular form, which on striking the ground usually break. In cattle the dung is voided in the form of a semi-solid mass (porridge), which flattens out upon striking the ground. Sheep and goats pass small firm balls resembling the fruit of the bay-berry. Swine and dogs pass feces somewhat more solid than those of cattle and frequently quite hard. In all animals the character of the food has a great influence on the appearance of the evacuations. For the horse we use the terms hard, firm, or loose balls, very moist balls, thick gruel-like mass, thin gruel-like mass, fluid, watery.

Increased firmness or hardness of the feces is observed in all febrile diseases, in constipation, and in the first stages of intestinal catarrhs. In severe febrile diseases of cattle (malignant catarrhal fever) and in obstinate constipation the feces are dry, hard and resemble peat in appearance.
Decreased firmness or abnormal softness of the feces occurs in all forms of diarrhoeas; intestinal catarrh, inflammation (mycotic and septic), dysentery of calves [hog cholera], influenza of the horse, severe tubercular affections of the mesenteric lymph glands.

The color of the feces is due to admixtures of bile, coloring matter in the food (chlorophyll in herbivora, haemoglobin in carnivora) and secretions. An admixture of fragments of bone, in dogs, produces a light gray color. An exclusive milk diet produces yellow feces (bile); green fodder produces a greenish hue; oats, straw and timothy hay produce a yellowish brown color; corn, beans, rye (especially when coarsely ground) produce a gray or yellowish gray color. In cattle the diet is much more varied than in the horse, consequently it is difficult to determine a normal color. It varies from a distinct green (in pastured animals) to lighter and darker shades of endless variety. Concentrated foods (Kraftfutter) tend to produce a more grayish color.

The following morbid changes may be observed:

The longer the ingesta are retained in the intestine the darker they become. After continued constipation the feces of horses and cattle assume a blackish brown, peat-like color.

A decreased admixture of bile (icterus) produces a gray, or light gray color resembling clay. Admixtures of blood produce a red, brownish red or chocolate color, sometimes almost black. A thorough admixture of the blood with the evacuated contents points to the occurrence of a hemorrhage in the anterior portions of the intestinal tract (hemorrhagic enteritis, dysentery, etc.). If the hemorrhage occurred in the rectum the blood adheres in the form of streaks or clots.

Discolorations are produced by catarrhal and inflammatory affections. In dysentery of calves the feces are gray or grayish white. Some medicines produce specific colorations of the feces: iron produces a black, calomel a green color.

Covering of the feces. In herbivora the feces are covered with
a thin pellicle of mucus which gives them a *shiny* appearance. This coating of mucus increases or decreases in thickness as the time during which the feces are retained in the intestine is increased or decreased. In intestinal diseases attended with extensive exudation from the mucous membrane the feces are not only coated with mucus but are mixed with it. This mucus may be glossy, colorless, yellowish (bile) or gray (epithelial cells and white blood corpuscles). Flaky or fenestrated coagulations on the surface of feces have their origin in the rectal mucous membrane (proctitis).

**Odor of the feces.** This varies with every species according to the food. Horse dung can hardly be said to have an offensive or repulsive odor, the dung of the ox has an odor peculiar to itself, and the feces of carnivora stink. Horse dung has a sour odor in digestive disorders when concentrated food was given in abundance. The feces of herbivora *stink* or have a *foul odor* when putrefactive processes go on in the diseased digestive tract. If albuminous exudates (blood) are present under these conditions the odor is carrion-like (hemorrhagic enteritis, distemper of dogs).

**The chemical reaction of the feces** has no particular diagnostic value. Horse dung, as a rule, has an acid reaction, a result of the decomposition processes going on in the large intestine. In digestive disorders and intestinal catarrhhs the acidity is often increased.

**Composition of the feces.** The composition of the feces as far as food particles and foreign substances are concerned demands careful consideration. In the first place the size of the undigested food particles must be considered, this indicates the degree of mastication or rumination to which they were subjected. In cattle the feces should consist of a homogeneous mass; coarse particles of food always indicate insufficient or faulty rumination: overloading of paunch, paralysis or inactivity resulting from inflammatory affections are the cause of the latter. In horses, on the other hand, coarse undigested particles of food occur normally in the dung, and faulty masti-
cation is not indicated unless the coarse particles are very numerous and whole or nearly whole grains of corn, etc., and bits of straw or hay can be recognized. The cause of the presence of coarse particles of food consists either in greedy feeding or in defective molar teeth. The degree of the defect bears a direct relation to the degree of coarseness of the food particles.

Foreign bodies in the feces of horses usually consist of sand, and in sheep we find wool.

Inflammatory products consist of mucus, blood, pus, croupous membranes; in chronic intestinal catarrh of cattle we often find small clots of blood.

In cattle and calves suffering with catarrhs or other inflammatory conditions of the digestive tract the soft feces frequently contain numerous gas bubbles; these are due to gas-producing putrefactive organisms which are particularly active in concentrated foods that pass rapidly along the digestive tract.

Any parasites of the gastro-intestinal tract may occasionally be met with in the feces, either entire (Ascarides, Oxyuris) or in segments (proglottides of tapeworms); sometimes the eggs only are present Distoma in sheep and cattle.) When Distoma are suspected a microscopical examination of the feces should be made. The eggs of these parasites are yellowish brown oval bodies or capsules provided with a lid, 0.15mm long, 0.1mm diameter).

The most common parasites of the digestive tract are as follows:

Horse: Gastrophilus equi and hemorrhoidalis, Ascaris megaloecephala, Strongylus arnatus [tetracanthus], Taenia mamillana, perfoliata, and plicata.

Cattle: Amphistomum conicum, Ascaris lumbricoides, Strongylus radiatus and ventricosus, Taenia denticulata and expansa, Tricocephalus affinis, Strongylus inlatus. In the bile ducts: Distomum hepaticum and lanceolatum.

Sheep: Amphistomum conicum, Strongylus contortus,
hypostomus, filicollis and cernuus, Taenia expansa, Trichoccephalus affinis, and [Taenia fimbriata]. In the bile ducts: Distomum hepaticum and lanceolatum, and [Taenia fimbriata].

Goat: Strongylus contortus, hypostomus, filicollis and venulosus, Trichoccephalus affinis, Taenia expansa.

Pig: Spiroptera strongylina, Trichina spiralis, Ascaris lumbricoides, Echinorhynchus gigas, Strongylus dentatus, Tricocephalus dispar. In the liver: Distomum hepaticum and lanceolatum.

Dog: Taenia echinococcus, coenurus, marginata, serrata, cucumerina, Bothriocephalus cordatus and latus, Ascaris mystax, Dochmius trigonocephalus, Trichocephalus depressiusculus.

The discharge of intestinal gases occurs only in horses and dogs; corn and green feed produce these gases in large quantities. In old cows, with chronic affections of the rectum or undue laxness of the sphincter ani, air is often sucked in during the act of expiration and expelled again at inspiration thus producing a sound as though intestinal gases were being discharged.

Addendum. An examination of the liver and spleen of domesticated animals is usually impracticable and in fact of little importance because primary diseases of these organs are rare. An enlarged liver in the dog can be felt in the region of the last rib, in the large animals palpation of the liver per rectum may, in rare instances, give valuable information. When greatly enlarged the spleen in the horse and the liver in the ox can thus be felt and tubercles, echinococci and tumors recognized.

Diseases of the Digestive Apparatus.

a. Mouth, Pharynx and Oesophagus.

Stomatitis. Here the morbid changes can be directly observed; three forms: stomatitis catarrhalis, st. vesicularis, st. ulcerosa.

Ptyalism. A continued discharge of large quantities of saliva without any assignable cause.

Pharyngitis, Angina pharyngea. More or less fever according to the character of the inflammation. Head held up, neck stiff. Appetite present but mastication and especially deglutition impaired. Food and
particulariy water ejected through the nose. Accumulation of saliva and food in the mouth, salivation; foreign bodies (food) in larynx, and cough. More or less symptoms of laryngitis, in serious cases dyspnea as a result of swelling of laryngeal mucous membrane.

Paralysis of œsophagus and pharynx. Dysphagia paralytica, difficult deglutition and absence of inflammatory symptoms.

Foreign bodies in œsophagus. Most frequent in cattle [but also observed in horses]; salivation, inability to swallow, choking, flow of saliva from nose; tympanitis in cattle. Foreign body in cervical portion of œsophagus can be seen or felt.

Œsophageal stenoses and diverticula usually develop slowly and gradually. Symptoms: sudden interruption in feeding, impaction of œsophagus with food; regurgitation, choking. Discharged masses are foamy but not sour.

Diseases of the teeth in animals produce trouble in feeding. Animals begin eating with apparent appetite but soon stop or continue with diminished interest, masticate slowly and carefully, smack their lips, pause, salivate, reject partially masticated food, swallow their grain whole, masticate roughage poorly, don’t eat a full feed, fees contain large particles of food, sometimes there is a tendency to diarrhoea. The following conditions of the teeth are of clinical importance, viz., sharp teeth, very oblique grinding surfaces (shear-jaws), an undulating or irregular set of teeth, projecting or depressed teeth; caries of the teeth, tartar deposits; periostitis alveolaris, tooth fistulae, neoformations on the alveolar perios-teum.

b. Stomach and Intestine of the Horse.

Acute dyspepsia. Lack or loss of appetite, particularly for grain; animals lick cold objects. Thirst is increased, buccal mucous membrane dry, animals yawn frequently.

Acute gastro-intestinal catarrh. Usually fever, animal is downcast, conjunctiva reddened, sometimes icteric. Appetite much impaired, frequent yawning, buccal mucous membrane reddened and clammy; feces at first dry, later diarrhoea; urine acid, without sediment, contains much indi-

Chronic dyspepsia. Chronically impaired appetite. Gastric disturbances

1) Simple chronic dyspepsia. Appetite for concentrated food (grain) impaired, otherwise normal.

2) Acid dyspepsia. Impaired appetite, but a craving for alkalies; licking whitewashed walls, nibbling at soiled litter.

3) Nervous dyspepsia. This occurs in easily excitable horses and consists in temporary disturbances of appetite after excitement.

Colic of horses. The term colic is applied in a general way to pathological conditions of the gastro-intestinal tract that cause horses to manifest symptoms of pain. As a rule they are caused by interrupted progress of the intestinal contents. The most important symptoms are those indicating pain, see p. 32, efforts to urinate and defecate, diminished peristalsis and retarded defecation. Sometimes impaction or torsion of
the bowels can be recognized as the causes (rectal examination). Before making a prognosis note carefully the condition of the conjunctiva and the pulse.

**Gastro-enteritis.** *Inflammation of the stomach and intestine.* High fever, great depression of the sensorium, mucous membranes muddy red; pulse very rapid, respiration increased. Complete loss of appetite, buccal mucous membrane hot, feces diarrheic, foul odor, and bloody. Rising is painful. Forms: gastro-enteritis rheumatica, toxica, cruposa, mycotica, parasitica.

c. **Gastric and Intestinal Diseases of Cattle.**

**Acute tympanitis.** Hoven, bloat. Rapid tympanitic distention of the paunch, food and drink are refused, defecation retarded. Increased and labored breathing, animals are anxious and restless.

**Dyspepsia.** Acute derangement of activity of stomach. No fever. Feed is absolutely refused, rumination suspended, belching, abdomen full, paunch contents firm, paunch movements slight, auscultation reveals sounds of bursting bubbles, feces dry, later on containing coarse food particles.

**Acute gastro-intestinal catarrh.** Fever, conjunctiva reddened, pulse frequent, appetite often entirely wanting, flanks sunk in, paunch movements incomplete. Milk secretion suddenly retarded.

**Chronic gastro-intestinal catarrh.** Gradual development and frequent change of symptoms. Appetite reduced, bloating follows a heavy feed, rumination interrupted. Defecation usually retarded, feces mixed with mucus, now and then diarrhoea. If disease is severe diarrhoea is continuous. Animal weak, falls off in flesh.

**Chronic tympanitis, chronic indigestion.** Periodically recurring attacks of slight bloating of paunch that continue for some time. Rumination and paunch movements retarded. Coarse food particles in feces.

**Dislocation of bowel.** 1. **Invagination** (telescoping) of intestine. Occurs suddenly and without external cause. Animals are restless, lie down, get up again, kick their bellies, groan. These symptoms attended with fever. Feeding and rumination cease, obstinate constipation, discharges of mucus and blood. Pains soon grow less but fever increases. Palpation per rectum usually enables us to feel the invaginated gut.

2. **Peritoneal hernia** or gut tie in the ox. Symptoms same as in invagination, in addition an abducted position of hind leg which is also extended back. Sacral region depressed. Palpation per rectum reveals presence, at anterior border of ileum, of painful doughy swelling, held in place by vestige of spermatic cord.

**Licking disease** of cattle and **wool eating** of sheep are peculiar chronic affections; afflicted animals have a habit of licking, nibbling, or even swallowing objects of a various nature, including indigestible and often loathsome and disgusting substances. At the same time there is loss of appetite and emaciation.

d. **Infectious Diseases with Localization in the Digestive Tract.**

**Rinderpest** is a readily transmissible, acute infectious disease, of cattle. It usually takes a fatal course. Period of incubation 6-7 days. High
temperature is the first symptom. Eyelids swollen, conjunctiva very red, respiration difficult, dirty yellowish nasal discharge, nasal mucous membrane reddened in spots, cough, moist rales, frequently interstitial pulmonary emphysema and cutaneous emphysema; complete loss of appetite, feces fluid, discolored; secretion of milk suspended, great depression, and general weakness of the body. Dark red areas on mucous membranes which (spots) become coated with grayish white layers, when the latter drop off and leave ulcerous erosions. Most animals die on the 5th or 6th day.

Stomatitis pustulosa contagiosa is an exanthema with a typical course. It occurs in the form of pustules, principally at the mouth, and is characterized by its mild course. Period of incubation 3-5 days. At first appearance of eruption there is fever, but this soon subsides. Horses refuse feed, they salivate, mouth painful to the touch. Within 2-3 days minute nodules or blisters appear on the mucous membrane; these are at first red, then gray or yellow, break open and form ulcers. Intermamillary glands swollen, conjunctivitis, now and then ulcers on the outer part (skin) of the lips, forearm and body; healing requires 10 days to two weeks.

E. Intoxications.

Lupinosis is an intoxication disease affecting the body as a whole. It is caused by a poisonous principle (lupinotoxin) which occurs in lupines. Diminished appetite, increased temperature, icteric coloration of conjunctiva, general weakness, cerebral depression. Urine yellow, contains bile pigments and albumin.

[Loco weed poisoning] An intoxication disease affecting chiefly the nervous system. Effects not noticeable until a considerable quantity of the "loco weed" has been eaten. Gait slow and measured, eyes glassy and staring, vision interfered with, convulsions when animal is excited; later on, general emaciation. Occurs in western States.]

In diagnosing diseases of the lungs percussion and auscultation of the chest is of fundamental importance. In diseases of the urinary apparatus we depend on the results of physical and chemical examinations of the urine. Experience has taught us that affections of the kidneys and urinary tract are not as common in animals as they are in man and consequently urinary analyses hardly merit the same importance that is attached to them by physicians. Besides this the entire field of kidney pathology in animals has received so little attention from investigators that our lack of knowledge is often evident to the diagnostician.

Results of a urine examination often enable us to diagnose
affections of other organs the abnormal products of which pass over into the urine.

The collection of the urine from animals is always attended with difficulties, in practice it is often impossible. As a rule the urine is caught up in a vessel during the natural act of the animal. In horses a vessel can be secured to the sheath and the urine thus collected. In female animals the use of a disinfected catheter is permissible.

In the course of the clinical examination we consider the urine first; if the latter shows material changes we also examine the urinary organs.

Accordingly we consider the following points and in the order given:

I. Manner of Voiding the Urine.

II. Examination of the Urine.
   A. Macroscopical examination.
   B. Chemical examination.
   C. Microscopical examination.

III. Examination of the Urinary Organs.

I. Manner of Voiding the Urine.

In our domestic animals urinating is a reflex act inaugurated by the stimulus of the urine on the mucous membrane of the distended bladder. As long as the distention of the bladder is below a certain point the reflex action of the sphincter vesicae which is also inaugurated by the pressure of the urine, supersedes that of the muscular coat, hence the one gives way to, or takes the place of, the other as occasion demands.

In adult male dogs only do we observe frequent and voluntary urination. For this act they prefer places used for the same purpose by other dogs. Their choice places are trees, the corners of houses, etc.

When urine is voided the bladder contracts and this is aided by the abdominal muscles. Every species of animal manifests peculiarities of its own in this act, but it is a rule that all animals stand while urinating.

Horses (both sexes) urinate only while resting and cease feeding for the time; not infrequently they emit loud groans.

Cows urinate similarly to mares, male cattle on the other hand urinate not only while feeding but also while walking; in fact, in these animals the act seems almost to be a passive one.

Old dogs and pigs (male) void the urine in an interrupted jerky stream.
1.) The frequency of urination depends on the amount of water imbibed, the amount of water lost by respiration, perspiration, and per intestinal tract; accordingly it varies very considerably. Healthy horses ordinarily urinate 5-6 times a day.

Abnormal frequency of urination occurs during increased secretion of urine (polyuria) in the course of diabetes, and in chronic inflammation of the kidneys, temporarily in the crisis of severe diseases (contagious pleuro-pneumonia of horse).

Urination is suppressed, when rupture of the bladder has occurred (urethral calculus) in oxen; to determine (in doubtful cases) whether or not an ox urinates a clean cloth is tied in front of the opening of the urethra.

2) Abnormally frequent attempts to urinate, only slight quantities of urine being passed at each attempt, stranguria. The cause of this is an abnormal irritability of the mucous membrane of the bladder and urethra. Such conditions are most frequently observed in the course of colic in horses where the distended intestines (impaction, constipation, tympanitis) exert a pressure on the bladder, or the sense of fulness of the abdomen causes the animals to make these attempts. Inflammatory conditions of the bladder (bladder diseases, stone and gravel, neoformations, poisoning with irritating substances) or of the urethra (applications of pepper) are much less common causes. Mares in oestrum often show these symptoms at the same time repeatedly protruding the clitoris.

3) When urination is painful the term dysuria is applied. The animals are restless, step to and fro, kick at their bellies, switch their tails, look back at the abdomen, groan, and void urine in drops or thin streams. The seat of the pain may be in the bladder or in the urethra (concrements, strictures, inflammations). Sometimes the pain is caused by abdominal pressure in peritonitis.

4) Retention of urine (ischury) is attended with accumulation of urine in the bladder. It is observed:

a) in obstruction of the urethra (concre-
ments, swellings, strictures, tumors). In such cases the urine is voided in drops or thin streams, and frequently with symptoms of pain.

b) in paralysis of the bladder; frequently associated with paralysis of the rectum and of the tail.

5) Inability to retain urine, incontinentia urinae, occurs as a result of paralysis or weakening of the sphincter of the bladder, or as a result of diminished sensitiveness of the urethral mucous membrane, thus suspending the reflex excitability of the sphincter. Most frequently observed in dogs in the course of distemper (spinal affection) but otherwise rare in animals.

II. Examination of the Urine.

A. Macroscopical Examination.

1) The quantity of urine voided depends on the same conditions that regulate the frequency of voiding it: on the average horses secrete 4—5 liters, cattle 6—12 and dogs \( \frac{1}{4} - 1 \) liter per day. As a rule we determine the quantity of urine voided daily by making an estimate. Collecting the urine for actual measurement is cumbersome and besides not exact.

A decrease in the quantity of urine is observed in
a) profuse sweating and in diarrhoea;
b) severe febrile diseases;
c) formation of large quantities of exudates in the pleural and peritoneal cavities;
d) weak heart and resulting diminished pressure;
e) acute and some forms of chronic nephritis.

An increase in the quantity of urine occurs in
a) diabetes insipidus [polyuria] (very marked) diabetes mellitus (which is rare), the daily average may be 40 liters;
b) most forms of chronic nephritis;
c) during reabsorption of profuse exudates and in the critical stage of severe infectious diseases.

2) The color. The normal pigments in urine have not
yet been thoroughly studied; although a number of them are known to exist, only one has been identified, viz. urobilin which is a product of bilirubin and is absorbed from the intestine. The color of normal urine is more or less yellow, increasing in darkness as the amount of urine decreases, and vice versa. In disease the color may become lighter or darker. We distinguish: yellow (pale yellow, light yellow, yellow), red (reddish yellow, yellowish red; red), and brown (brownish red, reddish brown, and blackish brown) urine. Other shades can also be recognized now and then.

_Pale_ water-colored urine always occurs in polyuria (physiological or critical polyuria, diabetes).

_Red_ urine is produced by admixture of blood, hemoglobin or methemoglobin. The particular cause in each case must be determined with the aid of the microscope.

_Greenish yellow_ or _brownish yellow_ urine or yellowish green foam is produced by bile-pigments.

_Dark colored urine_ (dark yellow or dark brown) is observed in all cases where the quantity has been reduced (concentrated), but it may also be due to admixture of blood.

_Color due to medicines:_ carbolic acid, black; aloes and rhubarb, brownish red.

3) _Transparency of urine._ Normal urine of the horse is always turbid; even the first few drops voided; toward the end it becomes even more so, frequently a light clay color. The turbidity is due to the presence of carbonates which precipitate in the bladder as the fluid becomes more or less condensed from reabsorption processes. When exposed to the air in a vessel the turbidity increases because the soluble acid calcium carbonate \((\text{CO}_3\text{H})_2\text{Ca}\) after giving off \(\text{CO}_2 + \text{H}_2\text{O}\) is converted to insoluble calcium carbonate \(\text{CO}_3\text{Ca}\). This conversion occurs most rapidly at the surface of the liquid, causing the formation of a thin fragile membrane at that place (crystals of calcium carbonate). Small granules of lime also precipitate and constitute a part of the sediment. Not infrequently these lime granules are imbedded in cylindrical masses.
of mucus that were molded in the uriniferous tubules. This normal *turbid* urine has an alkaline reaction.

Clear urine of the horse is always abnormal and usually has an acid reaction; upon cooling, however, it may become turbid. The turbidities consist of precipitated phosphates, oxalate of lime, and crystals of gypsum and uric acid salts; these dissolve upon heating the fluid. These salts can be recognized by means of a microscopical examination.

Abnormal turbidity may be due to the presence of organized elements (cells); recognized by means of microscopical examination.

In the ox, sheep and goat the normal urine is clear when voided but becomes turbid on standing; precipitation of monocarbonates.

The urine of the dog is clear in health, becoming slightly turbid after standing; due to precipitation of uric acid salts.

4) **Consistency of urine.** Normal urine of the horse is a rather thickish, slimy, viscous fluid; the viscosity being due to an admixture of mucine which occurs in the bladder. Besides this the cast off epithelial cells undergo a process of swelling and thus increase the consistency of the urine. Acid horse urine is always less viscid than such as gives an alkaline reaction because the epithelial cells swell more in the former.

All other domestic animals excrete a more watery urine.

5) **The specific gravity of urine** is determined with an aræometer, also called urinometer when specially constructed for this specific purpose.

The specific gravity for the

<table>
<thead>
<tr>
<th>Animal</th>
<th>Specific Gravity</th>
</tr>
</thead>
<tbody>
<tr>
<td>horse</td>
<td>1020–1050, average 1040,</td>
</tr>
<tr>
<td>ox</td>
<td>1025–1045, 1030,</td>
</tr>
<tr>
<td>dog</td>
<td>1020–1060, 1040.</td>
</tr>
</tbody>
</table>

The specific gravity varies inversely with the quantity. Aside from this an abnormally low specific gravity is
observed in diabetes insipidus (1001-1010) and in contracted kidney.

An abnormally high specific gravity is observed in all cases where the amount of urine secreted is below the normal (fever) and in acute nephritis. High specific gravity and increased quantity is observed only in diabetes mellitus.

B. Chemical Examination of the Urine.

1) The reaction of the urine of healthy animals depends on the kind of food: herbivora (horse, ox, sheep, goat) secrete an alkaline urine, carnivora (dog, cat) secrete acid urine. In omnivora the reaction depends altogether on the food.

In herbivora the alkaline reaction is due to the presence of acid bicarbonate of lime \( \text{CO}_3^2\text{H} - \text{Ca} - \text{CO}_3^{2\text{H}} \). The organic acid salts of lime which are contained in the food contain the acid radicles of malic, tartaric, succinic and lactic acids. These latter, upon being absorbed into the blood, become oxidized into acid carbonates which have an alkaline reaction.

In carnivora acid phosphates are the cause of the acid reaction; \( \text{PO}_4^2\text{H}_2\text{Na} \) and \( \text{PO}_4^2\text{H}_2\text{Ca} \); these come from the animal diet. Starving herbivora (hence such as live on their own flesh) have an acid urine.

Except in cases like the one just mentioned an acid reaction of the urine of herbivora is always abnormal. It occurs when the contents of the small intestine have an acid reaction—intestinal catarrh. When the contents of the small intestine have a normal (alkaline) reaction the acid phosphates in the food are not absorbed, and consequently do not enter the circulation, but when the reaction is acid the opposite takes place, the acid phosphates are absorbed and excreted by the kidneys, but the organic acid salts are not absorbed. An acid reaction, therefore, depends on the presence of acid phosphates and, in case of herbivora with good appetite, points to the existence of intestinal catarrh.
Abnormal alkaline reaction of the urine of herbivora and carnivora occurs in the course of fermentations in the bladder (catarrh) and is produced by ammonia, which is a product of fermented urea: \[ \text{CO(NH}_2\text{)}_2 + 2\text{H}_2\text{O} = \text{CO}_3\text{(NH}_4\text{)}_2 = 2\text{NH}_3 + \text{CO}_2 + \text{H}_2\text{O}. \] This ammoniacal fermentation can be recognized by its odor. A glass rod dipped in hydrochloric acid and held above the surface of the urine causes fumes to appear: \[ \text{NH}_4\text{Cl} = \text{Ammonium chloride}. \]

2) Albumin. Albumin is never a normal constituent of urine, i.e., in perceptible \[?] amount. Its occurrence must always be looked upon as a symptom of disease. As a rule it is secreted in the kidneys, with the urine (renal albuminuria); in rare cases blood or other morbid products of the urinary tract constitute its origin (accidental albuminuria).

The fact that normal urine contains no albumin, or at least no appreciable amount, is due to two factors: (1) the impermeability of the renal epithelial cells to albumin, (2) the degree of pressure exerted. When these normal conditions are altered, when the normal composition of the blood or the body temperature vary, albumin passes over into the urine. Hence renal albuminuria can occur:

a) As a result of changes in the renal tissues due to inflammatory or degeneration processes; here we find not only albumin present, but the quantity of urine may be increased by the addition of albuminous exudate.

b) In lowering of arterial pressure; the lower the pressure the easier can a diffusion of albuminous substances take place. Pressure is lowered in weak heart or in venous congestion (organic heart disease, emphysema). Both conditions, after existing for some time, in addition produce changes in the renal epithelium.

c) In fever albuminuria is always present. Several factors are active here. The lowered pressure may alone account for it; the elevated temperature facilitates the process; continued fever produces changes in the renal epithelium. In
case of severe infectious fevers a direct injury to the renal parenchyma probably occurs because in such cases the urine is very rich in albumin.

d) Mere changes in the normal composition of the blood, in the absence of any change of blood pressure or change of structure of the kidneys, may bring about albuminuria (leucæmia).

From what has been stated we can readily see that the mere presence of albuminuria does not necessarily indicate an affection of the kidneys.

Accidental albuminuria is rare and of little importance. We assume that the albuminuria is accidental when the filtrate contains large quantities of blood and pus corpuscles and epithelial cells and only a moderate quantity of albumin. In that case the proportionately small amount of albumin is supposed to result from partial solution of the cellular elements.

Of the various albuminous bodies occurring in urine serum albumin with serumglobulin are most frequently met with; less commonly albumoses are found either alone or in company with the above. These latter are albuminous bodies characterized by the fact that boiling does not precipitate them (pepton, propepton, hemialbumose). In a few cases we find hemaglobin and methemaglobin. For practical purposes the determination of the three groups mentioned is all that is necessary.

1. Chemical determination of albuminuria. For this use freshly voided urine; if not clear, filter.

1) Boiling test. Fill test tube to \( \frac{1}{4} \) its height with urine—if alkaline add a drop of acetic acid—boil and then add \( \frac{1}{10} \) its volume of dilute nitric acid (sp. gr. 1,18); a permanent precipitate = albumin. If a precipitate or turbidity produced by boiling disappears on addition of nitric acid = phosphate of lime.
2) **Heller's test.** The cold, filtered (and, if necessary, acidulated) urine is carefully poured on concentrated nitric acid, so as to form a layer on the same. If albumin is present a white or cloudy ring is formed in the test tube where the urine comes in contact with the nitric acid.

3) **Acetic acid ferro-cyanide of potash test.** To the filtered urine add a quantity of acetic acid and then a few drops of a 5% solution of potassium ferrocyanide; the presence of albumin produces a white precipitate.

If the addition of acetic acid produces cloudiness mucin is present; in this case filter the urine. The mucin may also be precipitated with acetate of lead before making the test.

The methods here given suffice for the chemical demonstration of albumin. For a quantitative determination of the albumin preserve the tubes containing the precipitate and thus the sediment, which consists of albumin, may be compared from day to day. For this purpose Esbach's albuminimeter is both simple and practical. See fig. 31. [Similar tubes can be obtained in the United States.] It is used as follows: Fill the tube with urine to the mark U (urine), then add reagents sufficient to fill the tube up to the mark R (reagents) as follows:
- citric acid 2.0 cc,
- procro-nitric acid 1.0 cc,
- distilled water 100.0 cc;

put on a stopper, shake well, and let stand 24 hours The sediment which consists of albumin can then be read off in fractions of 1-10%.

This instrument gives good results providing the amount of albumin present does not much exceed 0.2%; in that case dilute before testing the urine, say to 50% or 25%, by adding one or three volumes of water respectively; the result must then be multiplied by 2 or 4 according to the dilution.

**Albuminuria occurs:**

1) in all febrile diseases, especially in acute infectious diseases; contagious pleuro-pneumonia of the horse and in influenza;

2) in acute and chronic affections of the kidneys;

3) in venous congestion, hence in organic heart disease, emphysema and in the various forms of heaves;

4) in blood diseases; leukæmia, anæmia;

5) in nervous affections, epilepsy, eclampsia.

**II. Chemical determination of albumosuria.** This has only recently become of importance, since simpler methods have been found. The occurrence of albumoses depends on entirely different conditions than those which produce albuminuria. Albumosuria is not caused by inflammation of the kidneys, by circulation troubles nor by anaemia. Changes in the composition of the blood play the chief role here. Albumosuria occurs when purulent and fibrinous exudates are absorbed into the blood (pyogenic peptonuria) hence in the absorption stage of pneumonia exudates and in case of extensive pus formation in internal organs.
Albumoses are not precipitated by boiling nor by acids; their presence can be definitely determined only when other albuminous substances (albumin, globulin, mucin) are absent. Hence we must first test for these; if they are present they must be precipitated and removed by filtration. Albumin and globulin can be precipitated by boiling the previously acidulated urine. Mucin can be precipitated with acetate of lead.

The clear filtrate alone can be tested for albumoses: acidulate 500 cc of urine with hydrochloric acid and then add phosphomolybdic acid until no further precipitate is produced. Wash the precipitate thus obtained with 5% sulphuric acid, then with water, [this is done by filtering the precipitate and adding the 5% sulphuric acid and, later on, the water to the precipitate in the filter,] and then subject to biuret reaction. The precipitate thus treated is dissolved in a weak solution of caustic soda and then a 10% solution of sulphate of copper is added drop by drop; the presence of albuminoses produces a reddish violet coloration.

These tests are rather troublesome to make and hence not very practical for ordinary clinical purposes. We hope that simpler methods may soon become known, and then, no doubt, the detection of albumoses in the urine will become a more important factor in the diagnosis of disease.

III. Determination of hemoglobinuria. The fact that urine contains blood can often be recognized by its color alone; light red urine, resembling meat water (oxyhemoglobin), is rare. As a rule it has a muddy brownish red color (methemoglobin). A diagnosis cannot be based on the color alone, a chemical and microscopical examination is necessary.

Chemical determination. Add caustic potash or soda until the urine is distinctly alkaline, then boil as in albumin test. This converts the hemoglobin into hematin, it is precipitated with the earthy salts and gives them a reddish brown color.

The difference between oxyhemoglobin and methemoglobin must be determined with the spectroscope. Oxyhemoglobin gives two absorption bands between D and E, methemoglobin gives one between C and D.

The presence of hemoglobin may be due to admixture of blood as such (hematuria) or to hemoglobin alone (hemoglobinuria).

Hematuria is recognized by microscopic examination of the sediment and the detection of blood corpuscles. The admixture of blood can occur in the kidney, the pelvis of the kidney, the bladder or the urethra. It occurs most frequently in red water, acute nephritis, renal calculi, hemorrhagic infarction of the kidney, pyelonephritis, acute cystitis, cystic calculi.

Hemoglobinuria consists in the presence of hemoglobin (without the blood corpuscles) in the urine. The coloring
matter is derived either from the blood or the muscles. Accordingly we distinguish:

a) **hematogenic or toxæmic hemoglobinuria** in redwater of cattle and in Texas fever, also in bad cases of poisoning which cause decomposition of the red corpuscles, in extensive burns and in the course of severe infectious diseases.

b) **myogenic or rheumatic hemoglobinuria** in azoturia.

3) **Indican** = indoxyl sulphate of potash $C_8 H_6 N K S O_4$ and occurs in all urine in moderate amount. It is derived from the indol $C_8 H_7 N$ formed in the alimentary canal during putrefaction of albumin; indol is oxidized into indoxyl $C_8 H_6 N$. OH and then combines with sulphate of potash to form **indoxyl sulphate of potash** = indican.

If rapid putrefaction of albuminous substances takes place in the alimentary canal the amount of indican is increased; this is particularly the case in digestive disorders accompanied with diminished peristalsis, digestion and absorption. Constipation of the ileum produces the largest amount of indican; impaction of the colon on the other hand is attended with much less indican formation.

**Test for indican.** Take a few cc of urine and add to it an equal volume of hydrochloric acid; shake well, add, drop by drop, a fresh solution of chloride of lime or sodium hypochlorite—continuing to agitate the solution repeatedly; the blue colored indigo thus formed will precipitate. Adding chloroform and shaking the mixture thoroughly, then letting the fluid settle, causes the indigo and chloroform to settle to the bottom as an intensely blue fluid.

4) **Bile pigments.** Of the bile pigments bilirubin is most frequently found in urine; upon exposure to the air for some time it may be converted into biliverdin. Icteric urine is usually dark colored, golden yellow, yellowish brown or greenish yellow, the foam is yellow in contrast to the normal white.

**Test.** The qualitative determination is made according to Gmelin’s test. Pour 2-3 cc of concentrated nitric acid which contains some fuming nitric acid (NO$_2$) into a test tube, gradually adding the urine without mixing the fluids. If the urine is alkaline acidulate it before making the test. If bile pigments are present colored rings will appear at the point of contact of the fluids; of the colored rings the green alone is characteristic.

The test for bile pigments in the urine of the horse is
never as easy as in the urine of the dog, and in fact not as reliable because horse urine always contains other (in part unknown) substances that influence the reaction materially.

Normally the urine of domestic animals never contains bile pigments. They occur only in the following morbid conditions:

a) retention of bile in the liver attended with its resorption through the lymph vessels and its subsequent entrance into the blood; acute enlargement of the liver (*hepatogenic icterus*), occlusion of the ductus choledochus in intestinal catarrh (retention icterus).

b) in disintegration of large numbers of red blood corpuscles and the formation of bile pigments from the blood pigments (*hematogenic icterus*).

c) severe infectious diseases, extensive burns, internal hemorrhages.

5) **Grape sugar**, by means ordinarily employed can be detected in urine in disease only, viz. in diabetes mellitus. In horses this disease has been observed in a few instances only, in dogs it is common. We suspect the presence of sugar in polyuria when the specific gravity of the urine is high.

**Chemical determination.** If albumin is present this must first be removed by adding acetic acid, boiling, and filtering. Then add to 10 cc urine 1 cc caustic potash solution; if this produces cloudiness, filter again. Then add about 3 drops of a 10% solution of sulphate of copper. The appearance of a light blue color is in itself an indication of grape sugar; now heat the fluid, if grape sugar is present an orange yellow precipitate which gradually extends downward is formed at the surface; this is an oxide of copper.

**This test** (*Trommer's test*) is by no means reliable for horse urine because the latter contains other bodies that have a
reducing power: *Pyrocatechin*, etc. On the other hand substances that prevent the reduction (or precipitation) of oxide of copper may be present. Pure grape sugar, when added to horse urine, can sometimes not be detected at all by means of Trommer's test. In all cases of doubt we must therefore resort to the *fermentation test*, as follows:

Boil 20 cc of urine that has been freed from albumin, let cool and add a piece of baker's yeast as large as a pea, shake thoroughly, pour into a fermentation tube and close the latter with metallic mercury. Keep the tube at room temperature for 24-48 hrs. If sugar is present fermentation will set in and the CO₂ thus produced will collect in the top of the tube where the percentage is indicated by a graduated scale.

\[
C_6 H_{12} O_6 \rightarrow 2C_2 H_5 O H_2 + CO_2
\]

Grape sugar = Alcohol + Carbon dioxide

Fig. 33.

Carbonate of Lime.

C. *Microscopical Examination of the Urine*.

If the examination thus far conducted reveals any important alterations, we complete the same with the microscope. A *microscopic examination of the urine in diseases of the urinary organs is of even
greater importance than a chemical analysis.

Method. Pour some of the urine into a conical glass, previously stirring the same with a glass rod to be sure to get an average sample. The urine is then set away to allow the solid particles to settle out; with horse urine this is a rather slow process. To prevent decomposition during the process of sedimentation add a few drops of chloroform. Remove some of the sediment with a pipette and examine a drop on a slide, under the microscope.

a. Crystalline Constituents of Urine.

The reaction of the urine itself gives us a certain clue as to the character of the sediments. The normal alkaline urine of herbivora contains (see p. 151) carbonate of lime and small quantities of neutral phosphates $\text{Ca}_3(\text{PO}_4)_2$. Such sediment does not dissolve when heat is applied, but the addition of hydrochloric acid produces solution, and development of $\text{CO}_2$. The sediment which forms in the acid urine of carnivora consists of acid urates and acid phosphates which dissolve on being heated.

To determine accurately the nature of the crystalline sediment a microscopical examination must be made; the forms of the crystals indicate their nature. Amorphous salts can be recognized by micro-chemical tests only.

1) Carbonate of lime crystallizes in globules with radiate markings, if the globules are large a concentric marking can also be observed. Carbonate of lime crystals also occur in form of breakfast rolls, dumb-bells, whetstones and crosses. Amorphous powder of carbonate of lime can be recognized by
the fact that the addition of acetic acid causes an evolution of gas.

2) Oxalate of lime crystallizes in square octahedra that have strong light-refracting power, other forms occur but are not characteristic. Acetic acid does not affect oxalate of lime, hydrochloric acid dissolves it. It occurs in small quantities in alkaline urine, to a greater extent in acid urine, but is of no importance for diagnostic purposes.

3) Uric acid and its salts are normal constituents of the urine of carnivora but traces of them also occur in the urine of herbivora.

They commonly occur as an amorphous powder or in the form of crystals; whetstone, rhombic plates, pointed crystals, frequently occurring in the form of minute druses. A characteristic consists in the peculiarity that, on crystallizing, they attract the pigment of the urine which gives them a yellowish brown color. They dissolve in a solution of caustic potash, and they are precipitated in the form of rhombic prisms by the addition of hydrochloric acid.

4) Hippuric acid and its salts form rhombic quadrilateral prisms and needles which dissolve in hydrochloric acid. Normal constituent of urine of horses.

5) Triple phosphate of ammonia and magnesia $\text{PO}_4\text{MgNH}_4$ crystallizes in coffin-lid forms, dissolves in acetic acid without giving off gas. Does not occur normally in freshly voided
URINARY APPARATUS.

161

urine, but always forms when urine is exposed to the air for some time (fermentation). If found in fresh urine it indicates that ammoniacal fermentation has taken place in the bladder, cystitis, pyelitis.

6) Sulphate of lime, gypsum, occurs occasionally and in small quantity in the form of columnar prisms or plates in acid urine. It is abundant after internal administration of sulphates (Glauber salts). Of no importance.

b. Organized Elements of Urine.

In the diagnosis of diseases of the urinary organs these are of the greatest importance.

1) Epithelial cells in small numbers are found in normal urine, occasionally we find two or three pavement epithelial cells in one cover glass preparation. On the other hand the finding of epithelial cells from the uriniferous tubules (renal epithelia) is an exception under these conditions. Marked increase of epithelial cells is due to a pathological desquamation, hence is observed in catarrhs and inflammation of the membranes concerned. It is important to be able to recognize the origin of the cells by their form.

Renal epithelium is roundish or more or less cubical and granulated with proportionately large granules and is much smaller than the pavement epithelium of the pelvis of the kidney, the urethra and the bladder. They
occur singly or several united and not infrequently show signs of fatty degeneration. Their occurrence indicates a renal affection, but whether or not inflammation exists must be determined from the rest of our examination of the urine.

Pavement epithelia from the pelvis of the kidney, the urethra and the bladder resemble each other and cannot be distinguished as to their particular source. They are large, flat, polygonal, transparent, nucleated pavement cells. Those coming from the surface layers of the mucous membrane are more roundish or polygonal, those from the deeper layers are more oval, or cone shaped and may contain one or more protoplasmic projections that give them a toothed appearance. If a considerable number of such cells are present a catarrhal condition of the corresponding mucous membranes is indicated.

2) White blood corpuscles or pus cocci are spherical, granulated, nucleated cells that are cleared or become transparent when treated with acetic acid. They may have come from the kidneys or from the urinary tract; if from the kidneys we also find casts, if they occur simultaneously with numerous pavement epithelia and crystals of triplephosphate they come from the bladder.

3) Red blood corpuscles, when found in the urine, have lost most of their coloring matter, are pale and swollen. Those coming from the upper portions of the urinary tract have undergone these changes to a greater extent than those coming from the lower portions. Thorough admixture of red corpuscles with the urine, thus retarding sedimentation of the former, points to renal hemorrhage; blood casts always point to renal hemorrhage. Large masses or clots of blood, not thoroughly mixed with the urine, come from the bladder. An admixture of blood with the urine (hematuria) occurs in:

a) diseases of the kidneys: injuries, hemorrhagic nephritis, embolic nephritis;

b) diseases of the urinary tract: pyelonephritis, cystitis,
red water of cattle, cystic calculi, cystic tumors, injuries of the urethra.

4) **Urinary casts** are cylindrical bodies that were molded in the lumen of the uriniferous tubules. In the urine of the horse we find similar structures under normal conditions; they consist of strings of mucus of variable thickness, sometimes macroscopically visible and granulated with deposits of amorphous carbonate of lime. Addition of acetic acid causes the granules to disappear with the formation of $\text{CO}_2$. In acid urine we find uric acid salts instead. These so called *granule casts, lime casts, or cylinderoids* have nothing whatever in common with true urinary casts. They are especially common in the transition stage from oliguria to polyuria.

The true urinary casts are distinguished as follows:

a) **Hyaline casts**, slender, transparent, homogeneous bodies of various sizes and not sharply defined contour. They are rare, occur in health as well as in disease, are of no diagnostic importance and their origin is unknown.

b) **Epithelial casts** consist of renal epithelia agglutinated with exudates and forced out of the tubules by the pressure of the urine above them. Frequently red and white blood corpuscles are associated with them. Such cylinders, providing they occur in any appreciable numbers, always indicate inflammation of the kidneys. These epithelial cells may also have undergone fatty degeneration. If they contain no cells they are called *granular casts*, and have the same significance as the epithelial cylinders.

c) **Blood corpuscle casts** are formed of agglutinated red corpuscles and are due to renal hemorrhage. If these casts
contain many white corpuscles they indicate purulent inflammation (*pus-casts*).

5) Examination for micro-organisms is of value in case of fresh urine only, because urine that has been standing for some time will soon become filled with great masses of bacteria and mold fungi from the air. Large numbers of bacteria in *fresh urine* occur in pyelonephritis bacteritica and in chronic cystitis.

*Bacillus pyelonephritis bovis* will stain according to Gram's method. A cover glass preparation is made from the sediment of the urine, stained with gentian violet, rinsed with water, a few drops of Lugol's solution (Iod. 8, Pot. iod. 4, Aqua 100) added, then decolorized in alcohol. All bacteria that stain according to Gram's method have now assumed a deep blue color; while all the rest are decolorized. *Bac. pyeloneph.* appears as a rod with rounded ends, 2-3μ long and 0.7μ in diameter, evenly stained and usually occurring in little groups.

### III. Examination of the Urinary Organs.

**Topography.** In the horse and cow the left kidney only is accessible for palpation from the rectum, the right kidney lies further forward and cannot be reached by the hand. In the horse the left kidney extends back to about four inches behind the last rib and its inner border is separated from the median line by about the same distance. In the ox it is *loosely suspended* below the lateral processes of the first lumbar vertebrae. Sometimes it may be shifted over to the right side. In the dog the kidneys lie in the lumbar region, the right somewhat more anterior than the left; hence the left kidney can be more easily felt from the outside than the right kidney.

In palpating the kidneys follow the general rules for this method of examination (see p. 21). In pyelonephritis of the ox the kidneys are enlarged and firm, the ureters distended and their walls thickened and firm.

**Examination of the bladder.** Per rectum, in the horse and ox, is quite practicable; in the dog the examination must be made by external palpation. The extent to which the bladder is filled is of importance; if empty, in the horse and cow, it represents a soft pearshaped body lying on the floor of the pelvis. If well filled it can be felt as a distended body projecting far beyond the anterior border of the pelvis. To feel it the hand need not be inserted much further than to the wrist. The contents of the bladder can be removed by a steady
but moderate pressure applied with the hand, or by means of
the catheter; this may be important to determine whether
evacuation is possible. If the bladder is ruptured, which is
most common in oxen with urethral calculi, it is permanently
small and flabby.

Cystic calculi and tumors in the bladder can be recognized
with certainty only when this organ contains little or no fluid
contents.

Examination of the urethra is of consequence
in male animals, particularly in oxen, when the presence of
calculi may be suspected. As a rule these are lodged in the up-
per or lower portion of the S shaped curve. Pressure exerted
at the point where the obstruction is located produces pain.
As long as the bladder is not ruptured urine may dribble from
the distended urethra. Unfortunately catheterization is impos-
sible in the ox (sharp curves and narrow lumen of urethra);
in the horse and dog this examination is easy and reliable.

Diseases of the Urinary Apparatus.

Passive hyperaemia of the kidneys occurs as a result of chronic heart and
lung troubles. Urine is decreased, sp. gr. increased, albumin present. Symptons more conspicuous after exertions.

Acute diffuse nephritis. This is primary only in cases of poisoning with
irritating substances, otherwise it is a symptom of severe infections. Dys-
uria, stranguria, pain in the region of the kidneys, stiff gait and crooked
back. Considerable diminution of renal secretion (anuria), thick and
viscid, turbid, high sp. gr., acid, much albumin. Microscopic examination
most important; granular casts, renal epithelia and blood corpuscles.
Stupefaction, difficult breathing, edematous swellings.

Nephritis suppurativa. Secondary affection and usually of less impor-
tance than the primary disease. Intermittent fever, exhaustion, emaci-
tion, urine contains albumin, pus corpuscles and micro-organisms.

Chronic nephritis. No fever, develops very slowly. Anorexia, exhaus-
tion, emaciation. Pulse strong and hard, heart hypertrophied. Increased
amount of urine, low sp. gr., amount of albumin slight, few epithelial
cells and casts.

Cystitis, inflammation of the bladder. Continuous efforts to urinate,
hence small quantities or only a few drops are voided at a time. Urina-
tion painful, restlessness, groaning, animals remain for a long time in a
"urinating attitude." Urine cloudy, alkaline, slimy or purulent sediment,
ammoniacal odor. Pus corpuscles, red blood corpuscles, numerous pave-
ment epithelia, phosphate of ammonia and magnesia.

Retentio urina. Retention of urine. Complete (ischuria) or partial
suppression of urination; in the latter case it is voided in drops and with
symptoms of pain. Palpation of the bladder very important: distention, pain on pressure. Animals indisposed, inactive, do not lie down, appetite diminished, pulse increased, sweating. After rupture of bladder has occurred the pains disappear, animals feel more at ease, bladder is empty. Then come chills, high fever, urinous odor of transpired air.

**Incontinencia urinae.** Paralysis of bladder. Involuntary flow of urine, especially during motion.

**Hematuria** is a chronic productive cystitis of the ox, with tendency to hemorrhage. Blood corpuscles and clots in the urine.

**Hemoglobinuria** of the ox. Hemoglobinæmia. Fever, partial loss of appetite, diarrhœa. Urine light red to dark red, foams readily, urination painful, reaction at first acid, later on alkaline, contains hemoglobin, on boiling coagulates as gelatinous mass.

**Pyelonephritis bacterica boum.** This is a chronic purulent inflammation of the ureters and pelvis of the kidneys which spreads to the kidneys and is caused by a specific bacillus. Gradual emaciation and general depression. Intermittent fever. Urine thick and slimy, cloudy, gray or grayish brown, white and red blood corpuscles, casts, numerous pavement epithelia, crystals of triple phosphate, and bacilli, Bacillus pyelonephriticis boum. Stain according to Gram, 2-3μ long, 0.6-0.7μ in diameter, non motile, straight or slightly bent, rounded at the ends.

**Diseases of Tissue Metabolism.**

**Diabetes insipidus,** polyuria, pissing, is an independent disease in which large quantities of clear watery urine are passed continuously. Daily quantity of urine passed—as high as 30 liters. Urine as clear as water or slightly yellow, acid, sp. gr. 1001–1010, no albumin, little indican. Diminished appetite, desire for alkalies, [earth etc.] emaciation.

**Diabetes mellitus**, sugar in the urine, is very rare in horses, more common in dogs. Polyuria, ravenous appetite and thirst, rapid emaciation. Urine has high sp. gr., 1024–1045, and contains grape sugar.

**10. The Sexual Apparatus.**

Most of the organs of the sexual apparatus may, for the greater part, be subjected to direct inspection and palpation; their examination should be conducted according to general rules, care being observed that no parts are overlooked. For natural reasons the female sexual organs are more frequently affected with disease than those of the male. Most of these diseases belong to the field of obstetrics.

1. **Abnormally increased sexual desire** manifests itself not only by sexual excitement but also by psychic disturbances and altered sensibility, these often resembling diseases of the central nervous system. In females this condition is known as nymphomania, in males as satyrasis; continued erections of the penis is called priapism.
Mares are usually very ticklish and easily excited, if touched with the hand or harness they squeak or cry out, switch their tail, back up against persons or against the wagon tongue, kick, urinate, and can be used for their regular work only when special care is exercised. In rare cases they may act like dummies (general depression of the sensorium) and show symptoms of hyperaesthesia.

Cows show symptoms of great restlessness, are very excitable, bellow frequently, attack strangers, etc. Milk secretion is reduced, the milk has a bad taste and sometimes curdles when boiled.

In horses and bulls satyriasis manifests itself by restlessness and excitable, sometimes vicious, actions.

In many cases the cause of these conditions cannot be ascertained; in cows tuberculosis of the ovaries, in horses cryptorchism, is often the cause.

A. Female Sexual Organs.

II. The vulva. In bitches we observe swelling of the vulva and a bloody mucous discharge at the oestral period. In cows a tough glassy mucus is discharged just before parturition. This mucus comes from the neck of the uterus which it served to close.

A slight swelling of the vulva occurs in vesicular eruption of this region; small vesicles the size of a millet seed, and swelling may also occur in the adjacent skin in this condition. In puerperal septicemia the vulva swells conspicuously.

In torsion of the uterus the vulva is retracted and drawn into folds; however, exploration per vagina is necessary to definitely determine this condition.

Discharge from the inferior commissure of the vulva and soiling of the surrounding skin and tail are observed in:

a) catarrh of the vagina and uterus. In chronic catarrh (fluor albus) the discharge is of a thick slimy character and glassy; in acute catarrh the discharge is of a thin slimy character and discolored.

b) retention of the afterbirth; an ill smelling, discolored
fluid mixed with fragments of the foetal membranes is discharged.

c) vesicular eruption; the discharge is slight, slimy or purulent, sometimes mixed with blood.

d) tuberculosis; slight, chronic, muco-purulent discharge containing tubercle bacilli.

III. Vaginal mucous membrane. Whenever there is discharge from the vagina the vaginal mucous membrane should be examined.

Method. Grasp the tail near its root, raise it well up, and let it rest on the back of the other hand thus leaving the fingers of that hand free to open the lips of the vulva. In order to examine deeper lying parts an assistant should hold the tail and the operator can then insert his whole hand, which must be previously covered with oil. After thorough palpation in this manner the other hand may also be inserted, the vaginal walls spread apart, and their mucous membrane inspected; here artificial light may be of advantage. A vaginal speculum is not absolutely necessary for these examinations.

By means of direct examinations like these, affections of the vagina can best be observed and their character determined. In vesicular eruption yellowish gray nodules, vesicles or ulcers, the size of a millet seed, are found on the slightly and diffusely reddened mucous membrane. After healing, light specks that indicate the position of former vesicles and ulcers can be observed for some time.

In torsion of the uterus the vagina is contracted and the mucous membrane is drawn into twisted folds. The examination of the uterus and the explanation of changes in that organ belongs to the field of obstetrics.

IV. The udder. In the examination of cows the udder must never be neglected. Inquire at least as to quantity and quality of the milk. Observe the color of the skin and note any changes that may have taken place. The teats of cows and sheep may be affected with pox, in foot and mouth disease the teats of cows may be covered with blisters; we also find milk fistulae. Observe also the relative size of the different quarters of the udder and the condition of the surface; note the size, position,
and direction of the teats. In palpation each quarter should be separately felt, its size and consistency noted and sensitive or knotted areas observed. The teats should be soft and the milk canal should not be felt; if thickenings or swellings exist, their location, extent, size and form should be determined. Finally, milk every teat in order to determine the case with which the fluid can be drawn, notice the size of the stream and the character of the milk, whether it is clotted or bloody: A microscopical examination of abnormal milk is not necessary but may be of value in some cases. To determine whether a cow is “fresh” a microscopical examination of the milk for the colostrum bodies or corpuscles must be made.

B. Male Sexual Organs.

V. Diseases of the male sexual organs are usually of a surgical nature. In vesicular eruption we find vesicles, pustules and ulcers, or scars, on the penis. To examine stallions or bulls they may be lead up to a mare (or cow) which usually results in voluntary protrusion of the organ. In bulls manipulation with the hand may answer the same purpose. In glanders the testicles may reveal the presence of knots.

Diseases of the Sexual Organs.

Torsio uteri, torsion of the womb, of interest in internal medicine only when parturition or pregnancy is excluded. Animals are restless, kick belly with hind feet and have pains of labor. Examination of vagina gives necessary information.

Vaginitis (colpitis), inflammation of vagina. Symptoms vary much, according to degree and character of the affection. If inflammation is severe, general health is affected. Animals make frequent attempts to urinate; small quantities of urine passed at a time; animals remain long in a “urinating attitude.” Examination of vagina gives necessary information.

Endometritis, inflammation of the womb. Follows parturition; intensity of disease varies. General health more or less disturbed, fever, discharge from vagina which varies according to character of inflammation,
is observed particularly when animals lie down. Soiled tail, examination of womb according to general rules of obstetrics is always indicated.

**Mastitis**, inflammation of udder, garget.

1) **Mastitis interstitialis**. Fever and hot, rather firm and painful swelling of udder. Quantity of milk decreased, quality not affected.

2) **Mastitis catarrhalis**. Udder evenly enlarged, soft and elastic, hot. Teats swollen, hot, sometimes reddened. Milk resembling whey. Fever, loss of appetite. Infectious catarrhal mastitis is a special form of catarrhal mastitis, infectious, milk yellowish. Usually all four quarters affected.

3) **Mastitis parenchymatosa**. As a rule only, one quarter affected. Fever, appetite diminished, rumination interrupted, constipation. One quarter of the udder enlarged, firm, hot, sensitive. The teat of the affected udder is usually free from inflammatory symptoms, the milk secretion is greatly decreased, yellowish, contains muco-purulent flakes which usually contain numerous streptococci.

4) **Mastitis tuberculosa**. A few nodular enlargements, otherwise the udder is tough and flabby. Supramammary glands enlarged. Tubercle bacilli in milk.

**Vesicular eruption** [coital exanthemae] is an acute infectious vesicular exanthema of the mucous membrane of the vagina and the penis. Period of incubation 3–6 days. The vesicles develop into little ulcers.

**Mal du coit** [seen in U. S. in imported stallions]. Period of incubation 8 days to 2 months. Swelling of the vulva and penis, formation of vesicles and ulcers. Frequent attempts to urinate, increased sexual desire, urticariform swellings of skin, paralysis of hind parts.

### 11. The Nervous System.

Diseases of the central nervous system can be recognized only by the disturbed functions of its parts, a physical examination of the diseased parts is out of the question. We must therefore subject each function to a careful examination and draw conclusions as to the parts affected from the character of the disturbed physiological processes and conditions. To diagnose diseases of the central nervous system requires a knowledge of the location of the principal functions.

**Preliminary remarks on anatomy and physiology.** All efferent (motor) psychic (conscious and volitional) fibres originate in the cortex of the cerebrum, and all sensory fibres and fibres of special sense that conduct perceptible impulses terminate in the cortex of the cerebrum. The voluntary motor fibres (psycho-motor or cortico-muscular tracts, or simply pyramidal tracts) course from the cortex, through the pons Varolii to the anterior pyramids of the medulla oblongata. Here most of these fibres cross over to the opposite side (motor decussation) and go to the motor nerves of the extremities, through the lateral columns of the spinal cord. A few fibres that do not decussate as above described course along the anterior columns of the spinal cord and gradually pass over to
the other side like the rest but through the white commissure along the course of the cord.

Hence destructive processes in one hemisphere result in motor and sensory paralysis on the opposite side of the body.

The cerebral hemispheres are also the seat of all psychical activities; they are the seat of thought, volition, and sensation. Many motor centers are also found in the cerebral cortex and hence inflammatory conditions of this region may be attended with convulsive movements of the muscles.

The midbrain (crura cerebri, corpora quadrigemini and optic thalami) is the seat of the entire mechanism, harmony and equilibrium of all motions. Animals with both hemispheres removed, but with the midbrain intact can retain their equilibrium under the most varied conditions. Inflammatory irritation of the midbrain produces involuntary movements.

The cerebellum harmonizes or co-ordinates the movements of the body by regulating the succession of muscular contractions.

The spinal cord, besides conducting impulses to and from the brain, contains reflex centers which, when stimulated by afferent impulses, cause certain kinds of important movements (defense, flight, etc.). These movements are carried out independent of any action on part of the brain, as is easily proved on decapitated animals or where the spinal cord has been cut through. The thus isolated cord is as prompt as ever in producing reflex actions. The lumbar cord is the special center for defecation and urination, which also depend on reflex activity.

To be able to recognize normal conditions as well as to determine the presence and seat of pathological changes in the central nervous system observe the following points:

I. Psychic Functions.
II. Sensibility.
III. Motility.

I. Psychic functions. Since the cerebrum and particularly its cortex is the seat of all psychic activities, disease of the same must interfere with normal thought, feeling, and volition; movements, sensations and perceptions of peripheral parts occur unconsciously. The general mechanism, harmony and equilibrium of muscular movements may be entirely intact in this condition. Mental disturbances occur in a great many infections diseases, in febrile diseases in general, in the course of intoxications (poisonings) of varied kinds, and in local diseases of the brain itself.

Therefore, mental disturbances can be ascribed to local causes only when the possi-
bility of a general cause is eliminated. The disturbances in question consist of abnormal excitability or of abnormal depression.

Mental excitement is the result of cerebral irritation—as observed in acute cerebritis. Horses become restless, neigh, refuse to be lead, try to tear loose from the halter, step to and fro, paw, climb up into the manger, are anxious and easily frightened. Cattle bellow, snort, shake their heads, jump around, and into the manger. Dogs manifest their restlessness by an aimless running about, barking, howling and even biting. Pigs squeal, crawl under the litter, run about, climb over obstacles and jump up against walls. Similar symptoms are also observed in rabies, acute tubercular meningitis, malignant catarrhal fever of the ox and in anthrax.

Symptoms of mental depression frequently follow those of excitement. The animals droop the head, rest it on the crib or feeding rack, eyes half closed, take no interest in their surroundings, do not recognize familiar persons, run against obstacles, etc. In feeding they grab the food with the incisor teeth, chew slowly and "langidly," stop without a motive when food is still in the mouth and between the lips. In drinking they plunge their mouth into the water and often "chew" it. It is hard to make them move, they step around clumsily, wont "get over" when commanded to do so; they are hard to guide when driven, try to stay over on one side; if badly affected they cannot be used for service because they do not recognize commands. According to the degree of mental depression we recognize:

Dullness;
Somnolency, sleepiness, drowsiness, from which the patient is easily roused.
Sopor, profound sleep, rousing difficult.
Coma, profound insensibility.
A dulling of the psychic functions occurs in;
1) all acute infectious diseases: contagious pleuro-pneu-
monia, influenza, Rinderpest, anthrax, horse distemper, dog distemper, septicæmia, Rothlauf of swine, etc.;

2) all severe febrile diseases;

3) chronic affections of the brain: blind staggers, turnsick of sheep, second stage of acute cerebritis and cerebral hyperæmia;

4) poisoning with narcotics;

5) icterus, uræmia;

6) chronic gastric and intestinal affections of the horse.

Dizziness (vertigo) and syncope (fainting) are suddenly occurring temporary disturbances of consciousness and loss of equilibrium. Animals suddenly become unsteady in gait or standing position, sway, reel, stagger and sometimes fall to the ground. The cause may consist of the presence of parasites in the brain, hemorrhages, tumors, abscesses, passive cerebral hyperæmia (compression of jugulars by harness), aortic insufficiency or stenosis, also the action of glaring light ("ocular vertigo"), irritations of the external auditory meatus, and of the nasal mucous membrane by parasites, finally also of poisoning with certain plants.

II. Sensibility. The sensibility is tested by artificial stimulation, sticking a finger into the ear, flipping the nose with the finger, stepping on the coronet, pin pricks. In testing the general sensibility observe that no inflammatory condition exists in the part "tested." Peripheral irritation may give rise to spinal reflex actions, e. g. the hoof may be raised without any consciousness of the act on part of the animal either as to the act or stimulus producing it. For this reason the general behavior of the whole animal must be taken into account in testing its sensibility. If dogs cry out during such an examination, or test we may conclude that conscious feeling exists.

Decreased sensibility is called hypæsthesia, absence of sensibility is called anaesthesia, abnormally increased sensibility is called hyperæsthesia. Sometimes sensibility is retarded; this is
indicated when the reaction occurs an unusually long time after the stimulus is applied.

Hyperaesthesia is most frequently seen in old ticklish mares, also in lumbar prurigo of sheep and in the first stages of cerebritis.

Diminished sensibility is observed in chronic affections of the brain, immobility, tumors, second stage of acute cerebritis, parturient fever, second stage of cerebrospinal meningitis, and in narcotic poisonings.

III. Motility. In morbid conditions affecting the cerebral hemispheres only we observe no serious disturbances in motility because the mid brain and the cerebellum are the seat of co-ordinated movements.

Spasms, or cramps, are involuntary muscular contractions. Spasms of short duration, alternating with relaxations, are called clonic spasms; if they are very slight, uniform, rapid, and locally limited we call it trembling, if they affect large areas or extend over the whole body we call them convulsions. Clonic spasms are observed in partial and general epilepsy and in inflammatory affections of the brain and spinal cord (common after dog distemper). Tonic or tetanic spasms are muscular contractions that continue for some time without relaxation. They are characteristic for tetanus (lock-jaw) and strychnine poisoning, causing the body to assume a stiff position, especially the head, neck, ears, back, and tail. The mouth is closed as a result of contraction of masseter muscles, nostrils distended "trumpet like." Stiffness of the back without bending is called orthotonus, depression of spinal column and bending back of head toward withers, opisthotonus, spasms of the masseter muscles, trismus, spasms of the extensors of the limb, sawhorse attitude, muscles of the eye, prolapsus of the membrana nictitans, cramps of facial muscles, risus sardonicus (canine laugh). Tonic spasms in connection with clonic spasms are also observed in cerebro-spinal meningitis (cramp of the neck).

All spasms have their origin in the cortex of the cerebrum, the pyramidal tracts, or in the anterior cornua of the spinal cord.
Spasms originating in the cerebrum are attended with mental disturbances (epilepsy), not so in case of spinal spasms.

*Reflex spasms* are due to irritation of peripheral sensory nerve endings and are of spinal origin; they are observed when animal parasites occur in the intestines, during the period of shedding teeth, and in painful gastric and intestinal affections.

*Involuntary movements* may be due to irritation of one of the cerebral hemispheres or to paralysis of the opposite one, also to affections of the midbrain or of the cerebellum. They always proceed from circumscribed lesions and are therefore known as "symptoms of local origin." Sometimes involuntary movements occur in the muscles of the body and extremities, or the usual voluntary movements assume an involuntary character. In such cases animals manifest a desire to "go ahead," trot with *head raised or lowered*, run against obstacles; if they get into a corner they are at a loss as to how to get out, frequently they fall down in such a case. Sometimes, but more rarely, they *walk backwards*. If the cerebral disturbances are unilateral the symptoms tend to be the same. The animals walk in a circle (*Reitbahnbewegungen, riding school movements:*) they lie down and roll, turning on their long axis, or they fix their hind feet as a pivot, and walk around with their forefeet—*move like the hands of a clock*. Involuntary movements are most frequently observed in chronic and acute hydrocephalus, abscesses, hemorrhages, tumors and parasites in the brain. Turn sickness, [gid], of sheep is thus characterized.

In so called *riding school and clock hand movement* the coenurus is usually located on the surface of that half of the cerebral hemisphere facing the center of the circle; sometimes on the optic thalamus of the opposite side.

If affected sheep move forward with the head down and trotting motion of the forelimbs (*trotters*) the seat of the parasite is at the anterior end of the hemisphere or on one of the corpora striata.

Staggering gait, reeling, dizziness (*staggerers*) indicate that the parasite is located in or on the cerebellum.

When the coenurus is located at the base of the cerebellum it causes *rolling movements* of the animal.

If the animals hold their heads up high or backwards and move for-
ward rapidly, fall down, (sailors) the coenurus is located in the posterior portion of the cerebrum.

**Disturbances of the muscular sense.** The muscular sense enables us to recognize the position of the limbs and the extent of passive and active movements. As long as equilibrium is not affected, an animal suffering from disease of the cerebrum can be made to assume unphysiologic positions without being conscious of it, in fact they do this themselves, they interrupt movements before they are completed or go to the opposite extreme and make more extensive movements than occur normally.

In acute cerebritis and staggers horses sometimes assume peculiar positions of the legs, cross them, set them close together or one before the other; one may be set unduly forward, the other unduly under the body. When such positions are produced passively the animals make no attempts to change them. In moving about they raise their legs unusually high, (groping, wading walk) or not high enough and thus stumble when they meet obstacles.

**Paralyses** consist in partial or complete loss of power to bring about muscular contractions. Complete inability to move is called *complete paralysis*, if there is simply diminished power to produce movements we call it *incomplete paralysis* (*paresis*). According to the origin of the paralysis we distinguish *cerebral, spinal,* and *peripheral* paralyses. Paralysis of one side of the body is called *hemiplegia,* of both sides (both hind legs) *paraplegia*; paralysis of a single organ or part is known as *monoplegia.* Hemiplegia have their origin in the brain, paraplegia in the spinal cord, monoplegia in the motor centers of the brain or, and as a rule, in peripheral nerves.

In *cerebral paralyses* the cranial nerves are frequently also affected and psychic disturbances are present; we observe cerebral paralyses in:

1) **brain diseases:** acute cerebritis, cerebro-spinal meningitis, abscesses, hemorrhages (apoplexies), tumors, parasites.

2) **infectious diseases:** rabies, mal du coit (always), ex-
NERVOUS SYSTEM.

ceptionally in horse distemper, and in contagious pleuro-pneumonia of the horse;

3) in intoxication diseases: parturient fever, mycotic intoxications, brine poisoning.

Spinal paralyses are usually paraplegia which affect all nerves beyond the point of injury or disease and are always attended with sensory paralysis. Psychic disturbances are wanting. They are caused by:

1) spinal fractures;
2) diseases of the cord: inflammation, hemorrhage, tumors, parasites;
3) infectious diseases: dog distemper, rabies, rarely in contagious pleuro-pneumonia of the horse.

Spinal paralyses also affect the vegetative branch of the nervous system, since the lumbar cord is the center for the production of the contractions that produce defecation and urination. Hence paralysis of the rectum and bladder with the inevitable results (impaction of rectum and distention of bladder with urine) occurs. See pp. 137 and 148.

Peripheral paralyses are for the most part of a surgical interest. In internal medicine paralysis of the facial nerve, because it interrupts normal feeding, and paralysis of the recurrent nerve, because it disturbs respiration, are of interest. These two morbid conditions have been considered more in detail elsewhere.

Reflex excitability. Reflex movement is a temporary muscular contraction brought about by stimulating a peripheral (sensory) nerve ending. In order that reflex movement may occur the sensory and motor nerve fibres and the reflex center must be intact. Reflex movement is limited to one muscle or muscle group (simple reflex) or it may affect the whole body and in that case may be inco-ordinated (reflex spasm) or co-ordinated (motions of defense or flight). The following physiological reflexes are of clinical importance:
a. Reflexes of the brain.

1) Closing of the eyelids. The sensory fibres (trigeminus) of the cornea, conjunctiva and of the skin in the neighborhood of the eye conduct impulses to the medulla oblongata and from that point the facial nerve produces contraction of the orbicularis of the eyelids.

2) Sensitiveness to light on part of the pupil. Increased reflex excitability occurs in tetanus and in strychnine poisoning. Contracted pupil is observed in morphine, eserine, and pilocarpine poisoning.

Decreased reflex excitability in great mental depression, excessive pain and in dyspnea of high degree.

Dilated pupil (mydriasis) occurs in paralysis of the optic nerve (black cataract) and in paralysis of the oculomotor nerve (atropin poisoning).

b. Spinal reflexes.

3) Skin and tendon reflexes consist of short contractions (raising of leg) produced by striking the skin, tendons or bones: cannon bones, flexor of the carpus, inferior patellar ligaments, Achilles tendon.

4) Reflex centers for defecation and urination. See pp. 171 and 177. Disturbances of these centers occur in diseases of the spinal cord.

Diseases of the Nervous System.

Cerebral congestion. Hyperemia of short duration, fluctuating in character and entirely curable. Begins with stage of excitement; animals are restless try to force themselves forward or sideways, rear, kick, shake their heads, walk backwards, tear the halter strap, etc. After a few hours the stage of depression sets in: animals are stupefied, sad look of the eye, head down, disregard familiar commands.

Acute inflammation of the brain, acute hydrocephalus. Differs from congestion in its more pronounced symptoms and its longer duration. In the second stage (that of depression) we observe abnormal attitudes and movements, staggering, sometimes falling down and inability to get up again, sometimes attacks of raving madness. Temperature frequently increased, but fever may be absent. Feeding always more or less interrupted, especially the manner of feeding.

Blind Staggers. Morosis equorum. Hydrocephalus chronicus. This is a chronic apyretic incurable affection of the cerebrum which manifests itself by mental disturbances, and by impaired locomotion and sensibil-
ity. Pulse strong and full, number of heart beats never increased, but frequently diminished—a very constant symptom. Appetite usually good but eats slowly. Ability to work present to a limited degree. Examination for staggers. See p. 180.

Epilepsy. "Falling sickness" is a chronic disease of the brain characterized by paroxysms occurring at intervals and attended by sudden loss of consciousness and disturbed sensibility.

Dizziness, vertigo. This is a primary disease, occurring at intervals, characterized by interrupted equilibrium and due to circulatory disturbances in the brain.

Cerebral hemorrhage. Apoplexy. Sudden dizziness, involuntary movements, loss of consciousness, falling down, paralysis (hemiplegia and monoplegia).

Eclampsia is an acute epilepsy, ending in recovery or in death.

Turnsick is a disease of sheep caused by the presence of the larval form of Taenia coenurus in the brain. 1st stage cerebral excitement, 2nd stage-latent stage, 3rd stage is that of turnsick, characterized by symptoms of local brain affections.

Paralysis of the facial nerve. In case of peripheral paralysis the cheeks, lips and nasal muscles are paralysed, usually unilaterally; if paralysis is bilateral we have dyspnoea and difficulty in feeding. In case of central paralysis the upper eyelids droop, eyes cannot be closed and the auricular muscles are affected. Lumbar prurigo of sheep is a chronic, hereditary affection of the spinal cord characterized by hyperaesthesia, weakness and paralysis of the hind parts and by progressive emaciation, invariably leads to death.

Infectious Diseases with Localization in the Central Nervous System.

Lockjaw, tetanus, is an intoxication produced by the entrance of the products of the tetanus bacilli into the blood. Spasmodic condition of the entire skeletal muscles, animal is stiff, eyes retracted, membrana nictitans prolapsed, head and neck bent back, back depressed, tail erect. Sawhorse attitude of legs, hock turned out, producing bowleggedness. Spasm of masseter and pharyngeal muscles interfere with mastication and deglutition. Spasm of the respiratory muscles affects respiration. Great excitability; this aggravating the general muscular cramps. At first no fever, later on the fever is high. Pulse strong and full. Animals do not lie down, or when down they can not get up. Mental condition is normal.

Rabies is a strictly infectious disease characterized by disturbance of the central nervous system. 1. Initial stage. Dogs are restless, moody, easily frightened, want to be out of doors, depraved appetite. 2. Raving stage. Aimless running about, tendency to bite, sometimes break their own teeth in the act, voice changed to a barking howl. 3. Paralytic stage. Emaciation, lower jaw paralyzed, tongue extended, hind quarters paralyzed Horses show restlessness as in colic, neigh in a peculiar shrill or jelling manner, try to gnaw or bite the point of infection, bite the manger and not infrequently fracture the lower jaw in the act. Paralysis and death follow within three days. Cattle bellow and run against objects with their horns, frequently fracturing them. Sheep and pigs also manifest a desire to bite

Infectious cerebro-spinal meningitis. Disease is frequently introduced
with chills. Slight fever. Sensibility reduced, animals are drowsy, stumble and fall on slight provocation. Turning of eyes, jerking of muscles, later on paralysis. Tonic spasms of the cervical muscles; head drawn to one side.

**Intoxication Diseases.**

**Parturient paresis**, milk fever, is an acute auto-intoxication closely following the act of parturition, and characterized by cerebral paralysis. Begins with slight, temporary, cerebral excitement; after a few hours symptoms of depression and paralysis set in. Animals lie immovably in a characteristic attitude, see p. 34. Eyes closed, paralysis of muscles of head, tongue extended, rattling breathing, distention of abdomen, constipation, paresis of paunch. Lowering of external and internal bodily temperature.

**C. Specific Examinations.**

We resort to the specific examinations only when definite results cannot be obtained with the foregoing methods, especially in cases of differential diagnosis between similar diseases. In all cases the specific examinations are directed toward determining definite diseases; and the characteristics of these are specially considered.

**12. Body Movements.**

Many diseases are not observed until the animal is in harness or under the saddle, others become more conspicuous in their symptoms under these conditions. The rule is to examine animals while engaged in their accustomed occupation (blind staggers, balkiness). Draft horses should be examined when hitched to the wagon, riding horses under their rider. Unaccustomed work fatigues animals unduly and excites them. Sometimes fatigue and excitement make certain symptoms more conspicuous (roaring); in such cases we make an exception of the rule just given. In all cases we must observe that the animal is properly harnessed.

**I. Examination for Immobility.**

(Examination of so called dummies).

The symptoms of blind staggers are observable during rest but they increase when the patient is exercised. Mild cases of blind staggers can be recognized only after exertion
on part of the animal. It is of diagnostic importance that horses affected with immobility can be used for work, though in a limited degree, and that horses suffering with acute cerebral affections refuse to work or, if worked, symptoms of cerebral excitement follow. Again, horses with blind staggerers always have a low pulse, eat slowly but nevertheless eat a full feed. On the other hand, horses with acute cerebral affections have poor appetite and a high, or changeable, pulse.

In examining for blind staggerers the horses must be tested while performing accustomed duties and care must be observed not to excite them; in no case must they be subjected to unaccustomed work. It is advisable to drive or ride the animal oneself; notice the facility with which the animal is guided, effect of whip and spurs, tendency to go over to one side, ease with which animal moves forward or backward. As soon as the animal begins to sweat it is taken to a quiet place and rested, here we repeat a careful examination of the cerebral functions, (the animal's psychical condition); observe the expression of the eye, effect of surroundings, general attitude of the body, movements of the head, use of eyes and ears. To determine the degree of sensibility we resort to mechanical irritation: gently inserting a finger into the animal's ear, flipping the finger against the nose, stepping on the coronet, kicking against the cannon bone. Finally the animal's motility is tested to determine whether it voluntarily assumes unnatural positions (setting a foot abnormally forward or back) whether it advances or backs readily, follows its leader or not, halts without a command when the attendant leading it stops, etc. An important test is to attempt to cross the forelegs; horses with blind staggerers can usually be made to assume this position and throw their weight on their feet when thus crossed. To make this test the operator stands on one side of the animal, his legs spread so that one is in front, and the other behind the front leg of the horse, then grasps the foot of the opposite side (at the metacarpus and from
behind), forces the horse back a little to relieve the foot in question, pulls it over and crosses it in front of its opposite.

Fig. 42.

Examination of a Horse for Blind Staggers.

Quiet and gentle animals will sometimes remain standing in this position and even permit other insults, but from their general attitude it is plain that the reason for all this is not an abnormal mental state but rather extreme good naturedness. Animals greatly fatigued may show symptoms of a depressed sensorium but they are always of short duration.

A single symptom can never determine a
diagnosis, we must consider the animal's condition as a whole.

II. Examination for Balkiness.

Balkiness is refractoriness manifested in common and accustomed work. Hence a horse must be tested while at accustomed work, and we must proceed with utmost caution and quiet and avoid everything that might excite the animal. The examining veterinarian must be present during all manipulations and see to it that rough or improper treatment is avoided.

We first examine those parts of the body that bear the weight and pressure of the harness and see that no morbid or painful conditions exist; the animal is then properly harnessed. In case the harness does not fit it should be made so by shortening or lengthening parts that may require it, or by calling for another set of harness. Then the animal is tested in the capacity for which it is intended, single or double, as coach or draft horse, or under the rider, as the case may be. Active or passive refractoriness to reasonable demands is regarded as balkiness.

Young animals, such as are not yet sufficiently accustomed to work, also evince a certain degree of refractoriness, but, as a rule, if properly handled they will soon yield and obey willingly, especially if they are hitched with older and quiet horses.

III. Examination for Heaves.

Heaves is a chronic, a pyretic, and, as a rule, incurable difficulty of respiration. The definition is a forensic one and includes a number of entirely distinct morbid conditions of the respiratory tract and heart. Although we can, as a rule, by careful examination determine the exact nature, or anatomical lesion at the bottom of heaves it is customary, in Germany at least, to apply the term "heaves" to all of these conditions because "heaves"
is considered as one of those diseases the presence of which can set aside a contract of sale and is referred to under this name in all laws concerning it.

In examining for heaves we must differentiate between two entirely distinct groups of diseases:

1. Stenoses of the upper air passages;
2. Diseases of the lungs and of the heart.

1. **Stenoses of the upper air passages** as a rule do not manifest themselves until there is labored breathing, hence during work; they are characterized by the occurrence of a respiratory noise or tone. We must first determine whether or not acute morbid processes exist in the upper air passages and whether or not the animal has fever.

If the stenosis is in the nose it is frequently unilateral. When the animal is exercised a wheezing noise is heard—most distinct in inspiration, much less so in expiration. If the cause is unilateral the sound is unilateral and disappears when the nostril in question is closed, becoming more pronounced when the opposite one is closed.

**Stenosis of the larynx** is by far more frequent; as a rule it is due to a paralysis of the left recurrent nerve and the resulting inactivity and degeneration of the muscles which it supplies (laryngeal roaring). In rare cases a paralysis of the right recurrent nerve or a bilateral paralysis may exist; sometimes thickening of the mucous membrane or the presence of tumors may be the cause. An exact diagnosis of the cause of such a stenosis can be definitely determined only with the aid of the laryngoscope; but in 99% of all cases a left handed paralysis is the cause.

Except in rare cases laryngeal roaring is noticed only in forcible or increased respiration, and is then characterized by a harsh, sharp inspiratory noise or tone (wheezing, whistling, blowing, humming, roaring, snoring.) The respiratory noise is caused by the fact that deep and rapid inspiration causes the air current to force the paralyzed aryte-
noid cartilage and vocal cord into the lumen of the larynx and thus obstructs its free passage. Decreasing the volume of the ingoing current of air by compressing the nostrils causes the noise to cease. Pressure on the paralyzed arytenoid cartilage increases the noise. Pressure on the right (unaffected) cartilage increases dyspnoea to such an extent that inspiration is almost impossible, it ceases entirely or continues with a sharp wheezing sound, because the lumen of the larynx is now obstructed by both the arytenoid cartilages.

In examining for roaring the horse must be placed under conditions that force it to make rapid and energetic respiratory movements, it must be "worked hard," pull heavy loads over soft ground, or gallop. Exercising or riding are especially adapted for this purpose because we can control the position of the head, and thus influence respiration. Whether or not the animal is accustomed to this sort of exercise has no effect on the general result.

If the head and neck of the animal are well checked up and back, the points of insertion of the dorsal muscles are approximated and the action of the latter on the spinal column is reduced; now, in order to fix the spinal column the longissimus dorsi, the inspiratory and the abdominal muscles must be contracted with unusual force; this can be done only at the moment of inspiration. In expiration these muscles are relaxed and the animal loses, more or less, the control over its spinal column. It therefore makes an effort to reduce the expiratory period by rapidly and energetically following with the inspiratory movement. If only one arytenoid cartilage projects over the lumen of the larynx the inspiratory current forces it in, produces a stenosis and causes the respiratory sound. By turning the head toward the right the in-streaming current of air is directed on the left arytenoid cartilage and if the paralysis is only an incomplete one the characteristic sound is produced just the same.

This kind of treatment can never produce roaring in a healthy horse.

If existing lameness or the presence of acute affections of the respiratory apparatus or other organs make this method of examination impossible, the laryngoscope may do valuable service. See p. 101.

2. Chronic affections of the lungs and heart usually cause more or less respiratory difficulty even during rest. Most frequently this form of heaves is due to chronic bronchitis, alveolar pulmonary emphysema, chronic pneumonia, or organic heart diseases, which, as a rule, can be recognized as such. In diagnosing heaves it is important to
exclude, by means of a careful examination of all functional apparatus, any acute affections that may produce increased respiration; external painful conditions must also be considered. If an animal is lame the diagnosis "heaves" may appear uncertain.

To determine the existence of a respiratory difficulty the animals are worked in an accustomed manner and made to exert themselves to a moderate degree, at the same time we note the character and frequency of respiration. The horse should be driven or ridden in a quiet trot; a draft horse made to pull a moderately heavy load. Count the respirations every 5 minutes and let the animal work until it sweats, but not longer than 15 minutes. Then put the animal in a stable, count the respirations every 5 minutes and note when they return to the normal (the number counted before exercising).

In healthy horses the number of respirations runs as high as 50 or 70 per minute, sometimes even higher. Respiration occurs without exertion, the animals may now and then give a voluntary snort and take a few deep inspirations. In the course of at most 15 to 18 minutes after cessation of the exercise, the number of respirations should be reduced to that observed at rest.

"Heaves" horses, on the other hand, show increased or difficult breathing, dyspnæa, (see p. 84). Inspiration and expiration may be so difficult that the number is not increased, but the character of the respiratory movements enables us to recognize the dyspnæa. But as a rule the number of respirations, when animals are exercised as above described, runs up to 80 to 120 per minute and goes back to the normal very gradually. Not infrequently this requires 30 to 60 minutes. In chronic bronchitis a white foamy nasal discharge is observed.

IV. Examination for Epilepsy and Vertigo.

Epilepsy is a chronic cerebral disease that is characterized by paroxysms occurring at intervals and attended with interruption or loss of consciousness and sensibility. Verti-
Body Movement.

187

Go (dizziness) is a similar affection; it is an independent disease occurring in the form of periodical attacks, disturbed equilibrium and consciousness. The difference between epilepsy and vertigo is that spasms are absent in the latter.

The diagnosis of these two diseases is not difficult if one has an opportunity to observe an attack. In the intervals horses act perfectly normal. Sometimes certain known conditions bring about an attack; when making an examination of suspected animals we can often make use of this knowledge to bring on an attack. Horses may be hitched up and driven as on former occasions when an attack was observed, etc. The fit of the harness should be carefully inspected. Sometimes frightening or exciting the animal, or driving with the face turned toward the setting sun, or along streets sprinkled with alternating shade of trees and the glaring light of the sun, will produce an attack. If we cannot personally observe an attack we must base our diagnosis upon unobjectionable statements of witnesses.

Epilepsy. Characteristic epileptic spasms occur either only at the head and neck (partial epilepsy) or the whole body is affected (general epilepsy). Animals stop suddenly, distort their eyes, blink, spasmodically contract the muscles of the lips and face, raise their heads high and jerk them to one side, sometimes they step to and fro, or backward and forward, restlessly. In general epilepsy the spasms rapidly extend over the whole body; masticatory movements are spasmodic, the saliva is churned into foam, the animals grate their teeth, spasmodically distort their neck sideways, the muscles generally undergo spasmodic contractions, the animals stagger and fall and then the spasms may continue for some minutes. An attack may last from 1/4 to 15 minutes, the horses then get up and become quieted. The intervals between attacks are very irregular.

The above described idiopathic epilepsy must be distinguished from acute cerebral affections and from epileptiform spasms due to peripheral irritations (reflex epilepsy).

Vertigo. Attacks usually occur while animals are at work; they suddenly walk slower, nod and shake their heads, snort, raise their heads up and sideways, stagger, spread their legs and not infrequently fall down. Here they lie quietly, sometimes kick a little and then get up again. During the attack there is a loss of consciousness and sensibility, sometimes increased respiration and profuse sweating.

Attacks of dizziness due to congestion of the brain (compression of the jugulars) and to cerebral anemia (stenosis of aortic valves) do not belong under the head of idiopathic vertigo.

Diagnostic inoculations consist in the introduction of certain substances into the bodies of animals for the purpose of determining either the character of the substance or the condition of the animal's health. We base our judgment on the character of the result. For the clinician diagnostic inoculations serve merely to recognize a few infectious diseases; certain of these diseases have so rapid a course that the clinical symptoms cannot be relied upon to determine either their kind or character with any degree of certainty. Others which terminate much less rapidly do not show sufficient symptoms for a definite diagnosis. In these cases nothing save a correctly performed inoculation will serve to recognize the disease or to obtain an early diagnosis.

Diagnostic inoculations are always made with respect to certain well-known infectious diseases which our examination leads us to suspect. In performing the inoculation, therefore, we must consider the peculiarities of these diseases, we choose certain substrata for our inoculating material, we follow a certain method of inoculation and make use of particular animals.

For inoculation we use

1). material of known composition (tuberculin, mallein) in order to determine the condition of the animals from the resulting reaction.

2). substrata of diseased animals on test or experimental animals in order to determine the pathogenic character of the inoculated material.

Diagnostic inoculations are of particular value in the infectious diseases which follow.

I. Tuberculosis.

On the basis of the results of ordinary methods of clinical examination tuberculosis can be
Diagnosed in only a small per cent of affected animals. On the one hand only a few symptoms can be determined, on the other hand these symptoms are not characteristic because they also occur in other diseases. The discovery of the tubercle bacillus as the cause of tuberculosis is hardly of any value in the clinical diagnosis of the disease in animals. Morbid products from an affected organ (lung of cow) for microscopical examination, are difficult to obtain; the quantity is small and besides is swallowed by the animal as soon as it reaches the pharynx. But, an opportunity to examine pathological nasal secretions, ejections, vaginal discharges or pathologically altered milk must never be neglected. See p. 92.

Under these circumstances the experimental determination of this disease is of great importance. For this purpose we resort to the tuberculin test and to the inoculation of small experimental animals.

The tuberculin test. Tuberculin is the toxin of the tubercle bacilli, obtained from artificial cultures of the same. The tubercle bacilli are cultivated for six weeks in 5% glycerine beef bouillon at 38° C. [100.4° F.] The culture is then sterilized at 110° C [230° F.] and filtered through unglazed porcelain tubes. The filtrate is evaporated to 1/10 its volume and thus constitutes tuberculin. After these manipulations the tuberculin is absolutely free from germs and therefore it could never produce tuberculosis. Furthermore, it has no permanent injurious influence on either sick or healthy animals; during the tuberculin test the quality of the milk is in no way affected, but the quantity may suffer to the extent of a reduction of 10% or less, for a few days. In cattle with very advanced tuberculosis the disease has been observed to have become aggravated—according to reports.

Dose.* The tuberculin prepared as above described is

---

*This applies, of course, to the German tuberculin. In America the article is manufactured by a number of reliable firms. It should always be used as fresh as possible and the dose regulated according to the strength of the material. This is always indicated in the "directions for use."
diluted with 9 volumes of water to which \( \frac{1}{2} \% \) of carbolic acid has been added. Cattle and horses receive 5cc of this solution, yearlings 2.5cc, calves 1cc and dogs 0.5—1cc. It is best to obtain the material from the dispensary of a veterinary college a short time before using it.

**Technique.** The tuberculin is injected subcutaneously at the neck or in front of the shoulder. Before and after using, the hypodermic syringe should be disinfected with a 2\% solution of carbolic acid. Before inserting the hypodermic needle smooth down the hair at the point of injection. Disinfection of the injected area is not necessary if care is exercised otherwise. The best time for injection is in the evening between 9 and 10 o'clock. The bodily temperature of the animal to be injected should have been ascertained at noon of the day of injection and also just before injection. Eight or 9 hours after injection of the tuberculin, hence at 6 A.M., next day, the temperature of each animal should again be taken, and thereafter every two hours until the 18th hour after injection. Perhaps it is unnecessary to state that the temperatures should be recorded.

**Action.** In tuberculous animals the injection of tuberculin produces fever (reaction), healthy animals are not affected. If the temperature, after injection, at any time before the 18th hour, rises 1.5°C. 
\[2.7°F.\] above the highest temperature recorded on the previous day we may consider it as a distinct reaction and regard the animal tuberculous. If the increase is only 1.0°C. 
\[1.8°F.—2.5°F.\] the result is doubtful. If the rise is less than 1.0°C. \[1.8°F.\] it is to be regarded as a physiological variation and considered as of no importance.

According to A. Eber, in cattle that record no temperature above 39.5°C. \[103.1°F.\] before inoculation, a temperature of 40°C. \[104°F.\] or more after inoculation must be considered as a reaction; again, all temperatures after 39.5°C. and 40°C. \[103.1°F.—104°F.\] that are at least 1°C. \[1.8°F.\] above the highest of the preceding day must be considered as reactions.
Doubtful reactions are all those between 39.5°C and 40°C (103.1°F and 104°F) that are from 0.5° and 1°F higher than the highest temperature of the preceding day.

Temperatures less than 39.5°C (103.1°F) or, higher temperatures due to increases of less than 0.5° (9°F) are physiological.

Reliability. The tuberculin test cannot be regarded as absolutely infallible. About 90% of the tuberculous animals give a reaction. Animals in advanced stages of the disease frequently do not react. As a rule, however, a physical examination of such animals reveals symptoms which, when considered alone, would at least awaken suspicion as to the existence of the disease. Of the animals that do not respond to the tuberculin test about 10% [?] may be considered tuberculous. Nevertheless tuberculin is the best diagnosticum in our possession.

Inoculation of experimental animals. The milk of tuberculous cows contains tubercle bacilli when the udder is affected with tubercular processes, and also in some cases where tubercular processes in this organ seem to be absent. Microscopical examination of milk for tubercle bacilli is very difficult and the results unreliable, therefore we resort to intraperitoneal inoculation of Guinea pigs with the fresh milk of a suspected animal. If tubercle bacilli are contained in the milk tubercular nodules will develop on the peritoneum (omentum), spleen and liver in the course of two weeks. If the Guinea pigs do not die before, they are killed at the end of six weeks and carefully examined for tuberculosis.

2. Glanders.

In view of the great infectiousness and incurability of glanders the object of the veterinarian is to determine the presence or absence of this disease at the earliest possible date. However, horses affected with glanders show no symptoms or at least no characteristic symptoms in the early stages of the disease; for this reason horses that have been exposed to an infection with glanders are subjected to a mallein test, with the object of thus enabling us
to recognize the disease. If the animals show symptoms of the disease we endeavor to obtain some of the pathological products or secretions and with them inoculate experimental animals which are known from experience to be susceptible to the disease and develop it in a characteristic form.

**Mallein inoculation.** Mallein is the toxin of the bacilli of glanders and is obtained from their cultures in a manner analogous to that employed for obtaining tuberculin. The crude preparation is a fluid, obtainable from the manufacturer and injected in doses designated. It may also be obtained in the dry or powdered form and is thus injected in doses of 0.02—0.1 G. according to the weight of the animal. It is best to have the solution of the dry tuberculin prepared by the manufacturer.

**Technique.** This is the same as for tuberculin inoculation. Taking temperature of animal to be tested, two or three times at definite intervals before inoculation; inoculation between 10—12 P. M., and taking temperatures again on next day beginning at 5 A. M., and repeating every two hours until 6 P. M.

An increase of temperature equaling or exceeding 1.5° C. [2.7° F.] is considered as a reaction. The reaction is said to be typical if the rise in temperature is a rather rapid one, drops slightly, goes up again, and then slowly and gradually returns to the normal. The results of the mallein test cannot be compared with those of the tuberculin test, they are far less reliable.

**Inoculation of experimental animals.** A male Guinea pig is inoculated subcutaneously at the abdomen with nasal secretion, pus, etc. from a suspicious subject. If the inoculated material contains the bacilli of glanders a local abscess will develop at the point of inoculation and a firm hot swelling appear in the region of the thigh. After 2—4 weeks the Guinea pig is killed with chloroform. The presence of the characteristic nodules etc., of glanders, in the region of the point of inoculation and in the testicles confirms the diagnosis. Cats are also
suitable animals for test inoculations. We inoculate at the back of the neck.

3. Anthrax, Blackleg, Malignant Ædema and Wild-und Rinder-seuche.

On account of their rapid course the clinical diagnosis of these diseases is often impossible; besides, the symptoms of the different diseases are often much alike and hence a differentiation impossible. Although a microscopical examination of the blood (or exudate) of animals that died of one of these diseases suffices to recognize their character by finding the characteristic organisms, still there are cases where an inoculation alone can decide the question. We use rabbits for this purpose and inoculate them cutaneously (!) in the ear, with blood or exudate from the animal or carcass in question. If the rabbit dies the disease is either anthrax or Wildseuche because blackleg and malignant Ædema are not transmissible by means of cutaneous inoculation. The differentiation between anthrax and Wildseuche is made by a bacterioscopic examination of the dead rabbit. It is also worthy of note that in Wildseuche there is always a severe tracheitis.

In case the rabbit does not die, it is again inoculated; this time subcutaneously; if death follows, it was a case of malignant Ædema because rabbits are immune against blackleg. The presence of blackleg can be demonstrated by inoculating a Guinea pig with the suspected material; death following in a few days after inoculation.

We can expedite matters by simultaneously inoculating one rabbit cutaneously and another rabbit and a Guinea pig subcutaneously. If all three animals die we had anthrax (or Wildseuche) if only the two subcutaneously inoculated animals die it was a case of malignant Ædema, and in case it was blackleg only one animal, the Guinea pig, is sacrificed.

* If we desire additional proof by having the blood of a suspected anthrax carcass examined by a second person we

* [This method is commonly resorted to in Germany.]
may boil a potato, upon cooling cut it in halves with a sterilized (flamed) knife, apply some of the suspected material to the surface of one half, replace the other half, pack carefully and send it to the official bacteriologist. Blood sent in a flask, is usually not adapted for microscopical examination.

4. Rabies.

Suspected dogs are usually killed before they can be subjected to examination by an expert. A post mortem examination will then hardly enable us to make a definite positive diagnosis: we must resort to inoculation of a test animal. The diagnostic inoculation of a rabbit with the brain matter of a suspected dog is the only absolutely safe method of definitely determining the presence of rabies.

Method according to Johnne. The brain and cervical cord of the suspected dog are carefully removed. The medulla oblongata is severed from the brain by an incision, at the pons Varolii, made with a “flamed” knife. A piece of the medulla (size of a pea) is removed with sterilized scissors from the cut surface, placed into a sterilized porcelain vessel and thoroughly triturated with a small quantity of distilled water. Of this fluid two rabbits receive a few drops each into the anterior chamber of the eye; injected with a sterilized hypodermic syringe. If the hypodermic needle is fine and sharp and providing that the rabbit’s eye has been previously disinfected and anaesthetized the operation can be performed with little difficulty. We insert the needle at the border of the cornea directing it toward the median line. If the operation was carefully conducted a slight turbidity of the cornea which soon disappears is the only symptom that follows.

If rabies is present the first symptoms appear in from 2 weeks to 23 days; the animals are shy, crawl away, and show loss of appetite. After 12 hours paralysis and difficult deglutition is observed, the animals emaciate rapidly, grit their teeth
and cry when touched on the head. The disease thus produced by inoculation leads to death within 48 hours.

In horses the intermaxillary lymphatic glands are always subjected to an examination in diseases of the respiratory apparatus. Otherwise they are subjected to special examinations only when infectious diseases, glanders and tuberculosis, constitutional blood diseases (leucæmia) or the presence of malignant tumors (carcinoma and sarcoma) are suspected. Examination consists in palpation (conducted according to the rules given on p 21. The correct interpretation of these changes was discussed under "intermaxillary lymphatic glands."

When an examination is called for, the following lymphatic glands must be considered:

1) Intermaxillary lymphatic glands, lymphoglandula submaxillaris. In the ox these are of the size of half a walnut and are situated on the median side of the submaxilla, near its border and in the region of the point of insertion of the musc. sternomaxillaris.

2) Lymphatic glands of the parotid region, lymphoglandula parotideae. These are between and below the lobules of the parotid gland. In the ox they have the shape of a flattened tongue and a length approaching 6 cm.; this gland projects from beneath the border of the parotid gland, below the maxillary articulation.

3) The superior cervical glands, lymphoglandula cervicales superiores, and retropharyngeales are situated, as the name implies, on the posterior wall of the pharynx. In the ox they consist of a closely united packet, about 5 cm. long, under the lateral processes of the atlas, where they can be felt by placing the thumb on the lateral process of the atlas (both sides simultaneously) and thus pressing the finger tips behind the pharynx and then against the inferior face of the lateral processes of the atlas.

4) In the ox a few large lymph follicles in the depression in front of the shoulder (prescapular glands) and on the chest in front of the elbow articulation (prepectoral glands).

5) The lymphatics of the shoulder (prescapular glands) are covered by the mastoido-humeralis muscle in front of the scapulo-humeral articulation.

6) The precrural glands lie at the anterior border of the tensor fascia lata muscle; distinctly visible in cattle.

7) In the upper part of the flank of the ox four or five follicles as large as a lentil can frequently be felt subcutaneously.

8) The deep inguinal glands lie in the crural canal covering the crural vessels.
9) **The superficial inguinal glands** in the male animal at the neck of the scrotum on each side of the penis in the sheath. In the female as follows:

10) **The retro mammary glands** (glands of the udder) are especially well developed in the cow and are situated behind and above the udder.

In the healthy horse we can distinctly feel the intermaxillary glands, in the healthy ox the precrural glands, and no others; if any of the other glands are distinctly palpable we assume that they are enlarged.

The intermaxillary lymphatic glands of the horse are sometimes extirpated in order to subject them to a special macroscopical, or microscopical and bacteriological examination. For diagnostic purposes we resort to it in glanders only. We operate on the standing animal and resort to Schleich's anaesthesia.

### 15. The Blood.

The examination of the blood is of importance in a few rare cases only. A microscopical examination to determine the presence of certain infectious diseases is of value only in anthrax and Rothlauf in pigs, and even in these diseases the circulating blood contains only few organisms. However, in Texas fever it is of diagnostic importance, and in constitutional blood diseases it is equally invaluable.

The best way to obtain the necessary blood is to make a slight incision into the lip, with the point of a knife, observing care not to stretch the skin during the operation. If a larger quantity of blood is desired a hypodermic needle, inserted into the jugular vein answers the purpose better. [As far as annoyance of the animal is concerned tapping the jugular vein is preferable in all cases.] In practice we may limit ourselves to the microscopical examination; for this purpose a single drop of blood, placed directly on the glass slip or cover will serve the purpose. From this drop we can
make a few cover glass preparations, allow them to dry, take them home, fix, stain and examine them at leisure; or we may add a 0.3% solution of sodium chloride and

Fig. 43.

examine the blood in its fluid condition. Exact blood examinations are difficult and must be carried out with such care and minuteness that the practitioner is obliged to get along with the results of the simplest methods. For those who care to take up the study of blood examinations in detail we recommend "Jacksch-Klinische Diagnostik."

Number of blood corpuscles. In normal blood the proportion of white to red corpuscles is as 1:300 or 400. By using a 16 in. objective this gives us about 3 white corpuscles in each microscopic field. If a greater number of white corpuscles are present their number is morbidly increased (leucocytosis). To determine the exact number of corpuscles in a measured
quantity of blood certain kinds of blood counting apparatus are required (Thoma-Zeiss blood counting apparatus).

**Shape of blood corpuscles.** In pernicious anaemia the shape of the red corpuscles undergoes many changes; we find some unusually large in size (macrocytes) often containing a nucleus, others smaller than normal (microcytes) and still others of distorted form, pear and kidney shaped, angular or toothed, club shaped etc. (poikilocytes).

**Diseases of the Blood.**

**Pernicious anaemia.** Primary anaemia of adult animals with fatal termination. Fever not constant. Mucous membranes pale and somewhat yellowish. Pulse gradually becoming more rapid, appetite less and less. Increased weakness terminating in death. Blood watery, changes in red corpuscles characteristic; usually large ones with nuclei, and small irregular forms, seem elongated, angular or toothed, club or pear shaped.

**Leukæmia.** Chronic alterations of the blood and increased white corpuscles. Animals are languid, lazy, sweat easily, pale mucous membranes. Appetite grows less, pulse increases small. Heart tones metallic sound. Enlargement of lymphatic glands usually present. Sometimes ecchymotic hemorrhages in the mucous membranes.

**Texas fever.** Is an infectious disease of cattle, caused by Pyrosoma bigeminum [indirectly by the presence of Texas fever ticks, Boophilus bovis]. Period of incubation 10-15 days. High and continuous fever, rapidly progressing anaemia, red corpuscles reduced in number from 6 million to one million per cc. Hemaglobinuria. Fatal termination the rule.

**Pyroso ma bigeminum** is a minute pale protozoon of a roundish form found in the red corpuscles. It possesses amoeboid movement and can thus assume irregular shapes. When fully developed the parasites occur as two pear shaped bodies with their pointed ends converging.

![Different Stages of Development of Pyroso ma bigeminum in Red Blood Corpuscles.](image)

They are 2.5 to 4 μ long and 1.5 to 2 μ wide. In the circulating blood 1 to 2% of the blood corpuscles are infected, in the capillaries of the various organs more than half of them contain the parasites.
